Acknowledgements

I would like to thank my supervisors Dr Adam Cribbs, Professor Udo Oppermann and Dr Sarah Gooding for all of their support and guidance throughout my DPhil. Adam for teaching me about computational biology and inspiring me to pursue it as a career, Sarah for being a wealth of knowledge in multiple myeloma, and Udo for being a great group leader and offering me incredible opportunities.

I would also like to thank Dr James Dunford and Graham Wells for all of their knowledge in the wet lab, and generously giving up so much of their time to help me with my experiments (and only teasing me slightly for my *many* lab blunders). I am grateful and thankful to Dr Martin Philpott for his expertise in everything sequencing. I would also like to thank past lab members who greatly enriched my DPhil experience, Dr Filiz Senbabaoglu, Dr Chao Mike Jiang and Dr Henry Lee.

I'd like to thank Professor Afsie Sabokbar for all of her kindness and support during my time at NDORMS. I'm thankful to SABS directors, Professor Garrett Morris and Professor Charlotte Deane, for the fantastic opportunity to pursue a DPhil at the University of Oxford. I am also grateful for SABS and the DTC for teaching me how to code, and for introducing me to my fabulous SABS cohort.

I'd like to thank my partner, Evan Roberts, for helping me with all my computer related problems (from cellular automata, to environment issues, to taking it upon himself to speed my code up by 1 millisecond), and for procrastinating away from his own DPhil to do so. I am also tremendously grateful to SHCBC and its members for keeping me sane over the last four years, in particular, Beth Bryan and Julia Halligan. I'd like to thank my UCL pals, school friends and Karate family for being there for me, and giving me the chance to vent about my DPhil, even when it gets incredibly tedious.

Most of all, I'd like to thank my family and dedicate this thesis to them. Pamela James, for being the most supportive and caring mum in the world, and proof reading everything I've ever written, despite having no idea what most of it means. My dad, Michael Bott, for coming to all my football games (even at the age of 25) and being my biggest fan. And my sister and best friend, Alexandra James-Bott, who has the unique ability to cheer me up and make me laugh no matter the situation. I'm also grateful to the rest of my family, Daniel, Nancy, Spike, Auntie Lorraine and Gary.

The work in this thesis has been kindly supported by the Engineering and Physical Sciences Research Council (EPSRC) and GSK.

Abstract

Multiple myeloma (MM) is an incurable cancer of plasma cells, with an average five-year survival rate of approximately 50%. Over the last two decades, application of MM therapeutics, namely proteasome inhibitors (PI) and immunomodulatory imide drugs (IMiD), have almost doubled median survival time of MM patients. However, most patients will develop drug resistance. Acquired anti-cancer drug resistance remains one of the biggest barriers in the treatment of myeloma. Therefore, identifying novel therapeutics effective against MM, which are capable of overcoming drug resistance is of the utmost importance.

Recently, the prolyl-tRNA synthetase (ProRS) inhibitor, Halofuginone (HF), has been shown to be effective against cancer, including one study demonstrating effectiveness against MM. Halofuginone is an ATP-dependent, proline and tRNA competitive inhibitor of ProRS. Recently, a new proline uncompetitive, ATP competitive ProRS inhibitor, NCP26, has been developed. In this work the application of HF and NCP26 in MM is explored using both MM cell lines and primary MM patient samples. HF and NCP26 demonstrated cytotoxicity to both drug-sensitive and proteasome inhibitor (PI)-resistant MM cell lines in a dose dependent manner. The anti-MM effects of HF were abrogated in the presence of excess proline, whereas excess proline had no effect on NCP26 treatment. Using bulk RNA-seq, HF and NCP26 treatment was shown to activate the amino acid starvation (AAR) response, endoplasmic reticulum (ER) stress and downstream apoptotic signalling pathways in MM cell lines. NCP26 resistant MM cells also showed significant suppression of ER-associated elements, as well as reduced expression of *ATF4* (the master regulator of amino acid metabolism). Single-cell RNA- seq (scRNA-seq) was employed to further examine the effects of ProRS inhibition in primary patient bone marrow samples. scRNA-seq confirmed the activation of the AAR, ER stress and apoptotic mechanisms in newly-diagnosed and relapsed MM patient cells. From differential expression and composition analyses, HF and NCP26 treatment was shown to selectively target MM cells over the majority of immune cells, including NK cells, B cells and T cells. However, HF and NCP26 were also shown to elicit apoptosis in myeloid cells.

From this pre-clinical validation of ProRS inhibitors, it is clear that ProRS represents a new, promising target in MM.

A number of computational methods were developed to support the experiments conducted in this work. scRNA-seq and tRNA-seq analysis pipelines were developed and their performances were benchmarked. An MM classifier was also built to be able to automate cell type classification of MM patient scRNA-seq samples. The whole bone marrow (WBM) MM scRNA-seq datasets from this work were used to train the MM classifier. Publically available MM WBM scRNA-seq data was used to evaluate the performance of the MM classifier, and it was found to be fairly accurate at labelling MM cells.

Introduction

1.1 Overview

Multiple myeloma (MM) is an incurable cancer of plasma cells. MM accounts for 1-2% of all cancers and 10% of all hematological malignancies[1]. In 2020, it was estimated that the total worldwide incidence of MM was 160,000[2]. Over the last two decades, several classes of drugs have been approved for treatment in MM, including proteasome inhibitors (PIs), immunomodulatory imide drugs (IMiDs) and monoclonal antibodies. These are now standard drugs in the treatment of MM, and subsequently a drastic improvement in survival rates has been seen—median survival time for newly diagnosed MM patients has almost doubled in the last 10 years[3]. However, MM still remains an incurable disease, with patients eventually relapsing and becoming resistant to drugs they have previously been treated with. Drug resistance is one of the biggest barriers in the treatment of MM. Therefore, the generation of novel compounds effective against MM is important to extend progression-free survival of patients and work towards finding a cure to MM. This thesis aims to identify novel drugs effective against MM, which are capable of overcoming drug resistance to conventional MM therapies. It also aims to characterise the transcriptional landscape of MM, following treatment with these novel compounds, to ascertain the mechanism of action in MM and identify any potential side effects of treatment. MM is a heterogeneous disease with prominent interactions with the surrounding immune microenvironment. Therefore, MM cells

must be examined at the single-level along with other cells residing in the bone marrow niche, to fully capture the heterogeneity and immune interactions we see in myeloma.

This introduction will give a brief overview of the immune system, multiple myeloma (MM), and current MM treatments. The genome, epigenome, transcriptome and proteome will be introduced, followed by a review of the technological advancements and informatics tools used to decode them. Chapter 2 introduces the enzyme class: aminoacyl tRNA synthetases (aaRS) and reviews literature regarding their role in disease and the application of therapeutics targeting enzymes in this class. Next, literature surrounding the drug halofuginone, a Prolyl-tRNA synthetase (ProRS) inhibitor, is reviewed and its application in MM is considered.

1.2 The immune system

This thesis employs multi-omics techniques to assess the effectiveness and mechanism of action of novel therapeutics in multiple myeloma. MM is a cancer of terminally differentiated B lymphocytes (a type of white blood cell which acts as part of the adaptive immune system to fight infection). In chapter 6 single-cell RNA-sequencing is applied to MM bone marrow samples and the different cellular components of the immune system are discussed. Therefore, a brief introduction will be given into the different facets of the immune system.

1.2.1 The function of the immune system

Humans are exposed to millions of potential pathogens every day and would die without defences to be able to protect themselves from infection. These defences can be innate or adaptive. An example of an innate defence is the skin acting as a physical barrier between the outside world and the body. Innate responses are non-specific and relied upon as the first line of defence, however sometimes a more sophisticated, specialised response is required– called the adaptive immune response[4]. Both innate and adaptive immune responses rely on cells produced by the hematopoietic system. Hematopoiesis is the process in which the body

produces blood[5]. Postnatally, the major hematopoietic organs are bone marrow, lymph nodes, the spleen and the thymus.

1.2.2 Hematopoietic stem cell differentiation

All blood cells originate from multipotent hematopoietic stem cells (HSCs), located in the bone marrow (BM). Stem cells are precursor cells which can give rise to at least

Figure 1.1: Hematopoietic stem cell (HSC) differentiation. Multipotent HSCs divide and either self-renew or commit to common myeloid or common lymphoid progenitor cells. The committed progenitor cells then further commit to progressive restrictive progenitors, then finally differentiated cells such as B cells, T cells, macrophages and erythrocytes. In adult mammals, all cells shown develop in the bone marrow, except for T cells, which develop in the thymus, and macrophages, which develop from blood monocytes. Numerous dendritic cell phenotypes exist, they can be derived from lymphoid and myeloid progenitors, as well as monocytes.

one type of differentiated (mature) cell, with the capability of indefinite self-renewal. HSCs divide to either generate more HSCs (self-renewal) or committed progenitor cells. HSCs are thought to go through stages of progressive restrictive commitments, until they eventually become fully differentiated blood cells such as NK cells, T cells and macrophages (Figure 1.1). Firstly, HSCs lose self-renewal capacity, then commit to either a myeloid or lymphoid fate. Myeloid progenitors give rise to

monocytes, macrophages, granulocytes (neutrophils, eosinophils, basophils), mast cells, megakaryocytes and erythrocytes (red blood cells). Lymphoid progenitors give rise to natural killer (NK) cells, T cells and B cells. Both myeloid progenitors and lymphoid progenitors can produce dendritic cells (DCs)[5]. Each stage of commitment correlates with changes in expression of specific genes and transcriptional regulators, for the given subset of blood cells[6].

1.2.3 The innate immune response

The innate immune response, or ‘non-specific immunity’, is the first defence a host has to prevent infection from invading pathogens[4]. Innate immunity is found in all species, from early multi-cellular organisms to humans[7]. Innate immunity comprises physical barriers, such as tight junctions in the skin and epithelial/mucous membranes, as well as defensive cell-coordinated responses. Once foreign pathogens enter the host, numerous signalling cascades are initiated. Host cells are able to recognise foreign microbials by characteristic features, known as pathogen-associated molecular patterns (PAMPs). Once PAMPs are recognised by host pattern recognition receptors (PRRs), inflammatory responses are triggered and the invading pathogen is targeted for phagocytosis. Phagocytic cells, for example neutrophils, monocytes and macrophages (Figure 1.1), non-specifically engulf foreign pathogens, and use a combination of toxic molecules, degradative enzymes and antimicrobial peptides to kill the invaders. Additionally, various cytokines and inflammatory mediators are released. NK cells directly kill host cells infected by a virus[4] and an array of tumour cells[7].

In addition to its role preventing infection and eliminating invading pathogens, the innate immune response also stimulates the acquired immune response. Dendritic cells act as a functional link between innate immunity and the adaptive immune response. DCs become activated after they phagocytose microbes, they then cleave the microbial proteins, which bind to MHC proteins and together are transported to their cell surface. The activated DCs then carry the peptide-MHC complexes to lymphoid organs, which in combination with DC-secreted cytokines and expression

of co-stimulatory proteins and cell-cell adhesion molecules, activate T cells to initiate the adaptive immune response. Innate immunity is a fast response (minutes to hours), whilst adaptive immunity takes longer (days to weeks)[4].

1.2.4 The adaptive immune response

During evolution, vertebrates have also developed adaptive immune responses, in addition to innate responses[7]. Adaptive immune responses are specific to the pathogen that induced the response. Adaptive immunity is dependent on millions of B cells and T cells clones. Each clone shares a unique cell-surface receptor that can bind to a specific pathogen antigen. These receptors are antigen selective, they can distinguish between stereo isomers of the same molecule, and proteins differing by one single amino acid. Two classes of adaptive immune responses exist: antibody responses, co-ordinated by B cells, and cell mediated immune responses, co-ordinated by T cells[4].

T cells

T cells are predominantly produced in the thymus (hence their name). T cells are activated by fragments of partially proteolysed antigens displayed on the surface of antigen presenting cells (APCs), for example dendritic cells or macrophages. T cells recognise these fragments with their cell-surface T cell receptors (TCRs). All effector T cells interact with other host cells in the body, therefore have a short range of effect[4].

There are three main classes of T cells: cytotoxic (T_C) T cells, helper T (T_H) cells and regulatory T (T_{reg}) cells. Effector cytotoxic T cells express CD8 co-receptors ($CD8^+$ T cells) and act like NK cells by directly killing infected host cells, protecting against intracellular pathogens. Effector helper and regulatory T cells express CD4 co-receptors ($CD4^+$ T cells)[8]. Helper T cells work by activating other host cells in the innate and adaptive immune system, for example, by activating B cells to secrete antibodies and undergo class switching, by helping activate macrophages to destroy intracellular pathogens, recruiting neutrophils and promoting pro-inflammatory

cytokine production, and inducing naive cytotoxic T cells to become effector cells. Helper T cells can be further divided into T_H1 , T_H2 , T_{FH} and T_H17 subclasses[4, 8]. Regulatory T cells have the opposite function to helper T cells. T_{regS} prevent an excessive immune response that could be potentially harmful to the body. The development, activation and function of other immune cell types is suppressed by T_{regS} by secreting suppressive cytokines such as $TGF\beta$ and interleukin (IL)-10, and inhibitory cell-surface proteins. This means that the response to harmless ingested or inhaled antigens is limited[4].

B cells

B cells and plasma cells produce immunoglobulins (Igs). Immunoglobulins (Ig) are typically large Y-shaped proteins. The function of immunoglobulin molecules is to recognise and bind specific foreign antigens on pathogens. Binding of immunoglobulins to antigens renders the virus or microbial toxin inactive as it blocks their ability to bind to host cells. Additionally, Ig binding makes it easier for phagocytic cells to ingest the pathogen[4].

Some Igs in circulation are found in polymer formations of multiple Ig units, such as dimers or pentamers. A single Ig unit consists of two identical heavy chains and two identical light chains (Figure 1.2a). Each heavy and light chain has a constant region and a variable region. Heavy chains consist of one variable domain, and three or four constant domains. Light chains consist of one variable domain and one constant domain. Constant regions are found at the C-terminal end of Igs, and are a constant sequence for each given chain type. Variable regions are found at the N-terminal end of Igs. The variable regions of the heavy and light chain form the antigen-binding sites of Igs. The amino acid sequence variation of variable domains confer diversity for antigen-binding. Both chains also contain hypervariable regions, which come in direct contact with antigens. These domains are frequently mutated to allow for even more diversity of antigen binding[9].

Humans produce five main isotypes of immunoglobulin: IgM, IgD, IgG, IgA and IgE (named after the greek letter of their respective heavy chain; Figure

Figure 1.2: Immunoglobulin (Ig) diagram. a) A bivalent immunoglobulin molecule (specifically IgG). IgGs are comprised of two identical heavy chains and two identical light chains. Each chain has a constant region (κ or λ for light chains, and γ , ϵ , δ , α or μ for heavy chains), and a variable region. Hypervariable regions are domains on heavy and light chains that come in direct contact with antigens. These regions are frequently mutated to allow binding of diverse antigens. The two heavy chains are covalently linked by disulfide bonds in their hinge regions. Hinge regions offer flexibility which improves antibody-antigen binding efficiency. Heavy and light chains are held together by a mixture of covalent disulfide bonds (red) and non-covalent bonds. b) The five major classes of IgGs in humans: IgG, IgE, IgD, IgA and IgM, in their main secretory (antibody) form. IgE and IgM have no hinge regions and are composed of four heavy chain constant regions, not three. IgA and IgM are shown in their dimer and pentamer polymer formations, however other polymer formations are also found in the body.

1.2b). IgG can be divided into 4 subclasses, IgG1, IgG2, IgG3, and IgG4, and IgA can be divided into IgA1 and IgA2[9]. IgGs can either be membrane-bound (mIgGs) on the cell-surface or secreted (sIgGs, also called antibodies). Naive B cells only produce mIgGs— they do not secrete antibodies. IgM molecules are the first immunoglobulins produced by newly formed B cells. Membrane IgMs (mIgMs) associate with two signalling proteins Ig- α and Ig- β ; these complexes are known as B-cell antigen receptors (BCRs)[10, 11].

Each B cell's individual Ig antigen-binding site is determined by a process called V(D)J recombination, whereby separate Ig gene segments are joined together.

Separate loci, on three separate chromosomes code for κ light chain (chromosome 2), λ light chain (chromosome 22) and the heavy chains (chromosome 14). Each light chain locus consists of one or more coding sequence for constant (C) regions, and a set of variable (V) and joining (J) sequences. The heavy chain locus contains these elements plus an added diversity (D) gene segment. These gene segments are rearranged and brought together by site-specific recombination, aided by V(D)J recombinase enzyme. The RNA that codes for the whole Ig polypeptide chain is produced by co-transcribing the constant regions and variable regions together. From all the potential combinations of V, D and J gene segments, in theory, over 1.5 million different antigen-binding sites could be made. Diversity of antigen-binding sites is further increased by junctional diversification, whereby variable numbers of nucleotides are lost or randomly inserted at joining sites. This can increase diversity of variable coding sequences by 10^8 fold. However, this process can also shift the reading frame to produce non-functional genes. B cells that produce non-functioning IgS subsequently die in the bone marrow. Additionally, B cells that produce BCRs that bind too strongly to self-antigens in the BM undergo another round of V(D)J recombination to alter specificity; if this fails again then B cells die by apoptosis. Once a B cell can produce functional IgS, the V(D)J recombination process is switched off, and it only makes IgS with the same antigen specificity[4].

1.2.5 B cell maturation

Most B cells die in the bone marrow soon after developing, however some will develop in the bone marrow, where initial stages of maturation occur and then migrate to secondary lymphoid organs, such as the spleen. Within secondary lymphoid organs, numerous critical decisions on B cell fate are made, involving complex transcriptional networks, cell interactions, gene rearrangements, and mutations[12, 13]. As B cells develop and leave the bone marrow to populate peripheral lymphoid tissues, they undergo alternative mRNA splicing and start to express IgD BCRs in addition to IgM; they are henceforth known as mature naive B cells. IgM and IgD BCRs on a single mature naive B cell all contain identical antigen-binding sites. To

fully differentiate, B cells require antigen stimulation. Upon antigen stimulation, mature naive B cells are activated to differentiate into either Ig-secreting effector B cells (plasma cells) or memory B cells. Terminally differentiated plasma cells are the final effectors of the B cell lineage. Plasma cell differentiation involves the loss of expression of many genes, such as *CD19*, *CD20* and increased expression of plasma cell markers, such as *CD138* and *CD38*. Plasma cells have an extensive rough endoplasmic reticulum (ER), and have numerous genes involved in antibody secretion upregulated, including *XBP1* and *CHOP*, to enable the production of copious amounts of antibody[14]. Antibodies recognise and bind to the specific foreign antigen on the pathogen which stimulated their production. Binding of antibodies to antigens renders the virus or microbial toxin inactive as it blocks their ability to bind to host cells. Additionally, antibody binding makes it easier for phagocytic cells to ingest the pathogen[4].

Initially, effector B cells only secrete primary IgS (IgM and IgD) that have low binding affinity for antigens. However, further antigenic-stimulation, helper T cell activation, various cytokine secretions and activation-induced-deaminase (AID) enzyme activity, leads to processes which increase binding affinity of antibodies (affinity maturation) and diversify Ig isotype production (class switching). The main stages of B cell maturation can be seen in Figure 1.3.

Affinity maturation

Affinity maturation occurs through a process known as somatic hypermutation, whereby activated B cells form germinal centres and their variable regions mutate at a rate approximately a million times greater than spontaneous mutations. The enzyme AID is required for this process. Not many of the IgS that undergo hypermutation will have a stronger affinity for the antigen present. However, B cells produce BCRs and antibodies, both of which contain the same antigen-binding site. The B cells with a higher affinity antigen-binding site for the given antigen, will be preferentially stimulated at their BCRs. This in turn means that clones with increased affinity will preferentially proliferate and survive over other B cells with lesser affinity (similar to

Figure 1.3: A simplified diagram of B cell maturation. Once hematopoietic stem cells (HSC) commit to the B cell lineage, the cells undergo a number of changes in the bone marrow and secondary lymphoid tissues until they eventually commit to either becoming antibody-secreting plasma cells or memory B cells.

how evolution and natural selection works in population genetics). Most other B cells in the germinal centre will undergo apoptosis and die. After numerous repeated cycles of mutation and selection, the remaining effector B cell clones will have improved Ig affinity 10–5000 fold for the antigen during the course of the immune response[15].

Class switching

Class switching often occurs after somatic hypermutation has taken place, however they are independent processes, and B cells can class-switch without having already undergone somatic hypermutation[16]. Various cytokines produced by activated T helper cells, such as IFN γ produced by T_H1 cells, IL-4 and IL-5 produced by T_H2 cells and IL-21 produced by T_{FH}, can promote B cell class/isotype switching. Class switching allows effector B cells to produce the secondary class of Igs: IgG, IgA and IgE. Class switching is dependent on the mechanism ‘switch recombination’, where the constant heavy chain region undergoes a number of DNA cutting/rejoining events that bring any of the secondary Igs constant heavy chain exons adjacent to heavy VDJ exon[16]. The mechanism is not yet fully understood, however AID is necessary to facilitate class switching. Daughter cells from the same effector B

cell will then be able to produce different isotypes of Ig's, but all retaining their original specific antigen-binding site. In the early stages of an immune response, IgM is the main circulating antibody. After a lag period, IgG becomes the main circulating antibody in the blood[4].

The Ig isotypes have distinct immune functionality and tissue distribution. For example, a portion of IgG molecules can bind to macrophages and neutrophils, aiding in phagocytosis of microorganisms, it is also the only Ig that can cross the placenta; IgE molecules can bind to mast cells and basophils, and play a large role in allergic reactions and parasitic infections; IgA molecules are the main antibody in bodily secretions[4]. By each Ig class retaining the same antigen-binding site, this means that antigen-specificity can be distributed amongst the various isotypes. Therefore, a pathogen can be fought using an array of each isotype's biological properties[17].

Immunological memory

Following antigenic-stimulation, B cells proliferate and differentiate into either antibody-secreting plasma cells or memory B cells. Memory B cells are long-lived, quiescent cells that possess the ability to 'remember' past pathogens and respond quickly to the antigen[18]. Memory B cells express BCRs of various Ig isotypes. Plasma cells appear to consist of two distinct categories: short-lived plasma cells, which have life-spans of several months and are located in extrafollicular locales such as in medullary chords of lymph nodes or the red pulp of the spleen, and long-lived plasma cells (LLPCs), which have a much longer life-span, ranging from months to decades[19, 20]. LLPCs are mainly found in the bone marrow[19, 20]. At the end of a primary immune response (first exposure to an antigen), the majority of antigen-specific B cell clones undergo apoptosis, leaving memory cells and LLPCs as the only remaining cells from the B cell lineage. Upon second exposure to an antigen, these cell types speed up the secondary immune response and reduce the lag period seen in the primary immune response. Existing memory B cells, which already possess high-affinity receptors for the given antigen, are expanded for immediate differentiation into short-lived plasma cells that can secrete high affinity

antibodies. Human memory B cells can be split up into three main categories: IgM⁺ only, IgM⁺IgD⁺, and class switched IgG⁺ and IgA⁺[18]. IgG⁺ memory B cells are more likely to differentiate into plasma cells following re-infection. Immunological memory is the basis for the success of vaccinations, where previous exposure to a weakened/dead microorganism or its protein/toxin stimulates an immune response and ‘readies’ the body for if it encounters the full disease.

1.3 Multiple myeloma

1.3.1 Multiple myeloma cells

Multiple myeloma (MM) is a malignancy of terminally differentiated plasma cells. It is characterised by aberrant proliferation of clonal, long-lived plasma cells in the bone marrow[21]. The large accumulation of MM cells displace healthy cells in the bone marrow. Under normal conditions, plasma cells produce antibodies that fight infection as part of the adaptive immune system. However malignant plasma cells (MM cells) produce large amounts of abnormal antibodies that are unable to fight infection, coined ‘paraproteins’ or ‘M proteins’ (Figure 1.4). Only

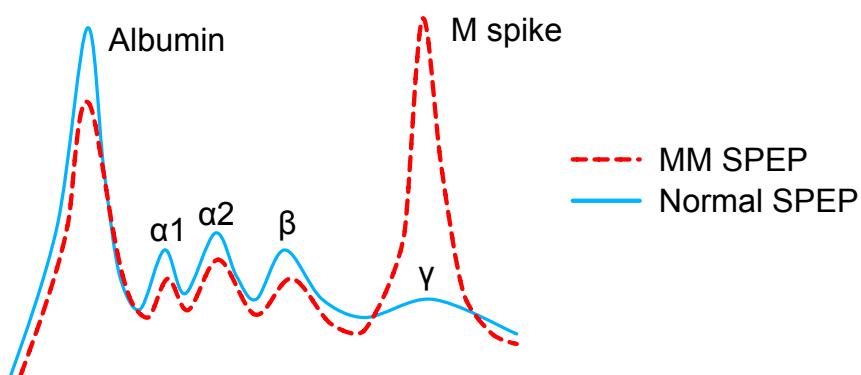

Figure 1.4: Diagram of serum protein electrophoresis (SPEP) for a healthy individual and for a multiple myeloma (MM) patient. Based on proteins’ electrical charge, size and shape, SPEP separates proteins in blood. A large peak is recorded for albumin (the most abundant protein in blood), followed by lower levels of the other proteins, grouped into α_1 , α_2 , β and γ regions. Antibodies are located in the γ region. The large quantities of a single type of antibody (M protein) produced by MM cells cause a distinct, narrow ‘M spike’ in the γ region.

one type of Ig is overproduced by a MM patient. The type of Ig overproduced

varies from patient to patient. Paraproteins can either be whole Iggs or just the light chain (κ or λ) part of an Ig, or more rarely, just the heavy chain (Figure 1.2a). A patient's myeloma type is named after the abnormal Ig isotype they are making. IgG is the most common type, followed by IgA and light-chain-only myeloma. IgM, IgD and IgE are very rare myeloma types[22]. Increased IgM can also be seen in other B cell malignancies such as Waldenstrom's macroglobulinemia, which is a rare proliferative disease of B lymphocytes.

Malignant MM cells vary from healthy plasma cells considerably. The transformation from healthy plasma cell to MM cell is a complex multi-step process, involving numerous genomic, epigenomic, transcriptomic, proteomic and metabolic changes[23–26]. Examples of such genomic changes include a rearrangement of the 14q32 locus (where the Ig heavy chain gene is located)[27] in approximately 60% of patients, as well as rearrangements in *MYC*, *CCND1*, *FGFR3* and *CCND3*[23]. Fluorescence in situ hybridization (FISH) testing is often performed on upon MM diagnosis and at time of relapse, to detect certain genetic alterations and aid in risk stratification of patients[28]. Deletions of chromosome 13 and mutations in *NRAS* and *KRAS* are also frequently seen in MM. Gene expression changes in MM cells include loss of *CD19* expression and aberrant *CD56* expression. DNA methylation and histone modifications have also been indicated as crucial regulators of MM pathogenesis.

1.3.2 MM microenvironment

MM cells typically grow within the bone marrow (BM). This is often referred to as their BM niche or BM microenvironment. The surrounding microenvironment plays a large role in supporting the progression of MM. The BM microenvironment is comprised of a cellular compartment (immune cells, endothelial cells, osteoblasts, osteoclasts and stromal cells) and a non-cellular compartment (the extracellular matrix (ECM), cytokines, chemokines and growth factors)[29, 30]. MM cells interact with their surrounding environment. These interactions influence the migration, differentiation, survival, proliferation, and response to therapies of MM cells.

1.3.3 Epidemiology

MM accounts for 1-2% of all cancers and has the second highest incidence of hematological malignancies, after non-Hodgkin's lymphoma[1]. MM is rare in individuals under the age of 40, with a median age of 70 at time of diagnosis[31, 32]. MM is more prevalent in males than females and is around twice as common in black populations than in Caucasian or Asian populations[33]. The average incidence rate is approximately 1-6 cases per 100,000 individuals[31, 32, 34], with the highest age-standardised incidence rates in the regions of Australasia, North America, and Western Europe[35]. Five-year survival rate of MM patients is approximately 49%, whilst approximately a third of MM patients survive ten years or greater[36, 37].

1.3.4 Presentation of precursor states

All cases of MM are preceded by asymptomatic precursor states, monoclonal gammopathy of unknown significance (MGUS) and smouldering multiple myeloma (SMM). However, only some patients with SMM or MGUS progress to active MM.

MGUS is a pre-malignant condition where patients have the presence of monoclonal immunoglobulins in their blood or urine, <10% clonal plasma cells in their bone marrow, but lack any myeloma-related end-organ damage[38]. Patients with SMM have between 10% and 60% clonal plasma cells in their bone marrow, serum monoclonal immunoglobulin of ≥ 3 g/dL, and like MGUS, have no signs of end-organ damage[39]. Progression risk of MGUS into symptomatic MM is about 1% per year, whilst progression risk of SMM to MM is higher, at around 10% per year for the first 5 years, after which it decreases[40, 41].

1.3.5 Presentation of active MM

There are multiple classifications of active MM. The International Myeloma Working Group's definition[42] is as follows: greater than 10% clonal plasma cells located in the bone marrow and one or more myeloma-defining event or biomarker of malignancy. Myeloma defining events consist of evidence of end-organ damage that

can be attributed to the surplus of M protein and clonal plasma cells, namely the CRAB features:

- Hypercalcemia (C)
 - Increased serum calcium
 - Symptoms include: excessive thirst, nausea, constipation, tiredness, loss of appetite, excessive urination and confusion
- Renal dysfunction (R)
 - Increased serum creatinine levels
 - Symptoms include: nausea, loss of appetite and weight loss, dehydration, tiredness and lack of energy, swollen feet and hands
- Anaemia (A)
 - Anaemia of unknown cause
 - Decreased hemoglobin levels
 - Symptoms include: breathlessness and tiredness
- Bone lesions (B)
 - Unexplained and persistent bone pain (often in the back, shoulders, hips or ribs)
 - Osteolytic lesions found using skeletal radiography, computerized tomography (CT) or positron emission tomography (PET)-CT scans
 - Symptoms include: pain, breaks/fractures, and spinal problems.

MM patients are also more prone to infections, and often take longer to recover from illness. This is because MM patients do not have enough healthy white blood cells to fight pathogens effectively. Biomarkers of malignancy include greater than or equal to 60% clonal plasma cells in the BM, an involved-to-uninvolved

serum free light chain ratio greater than or equal to 100, and more than one focal lesion on an MRI study[42].

It is currently unclear what causes the malignant transformation between precursor states and active MM. Certain factors have been identified as risk factors, including point mutations in genes such as *NRAS*, *KRAS* and *MYC*; chromosomal copy number variations, for example deletion of chromosome 13; a large array of up-regulated transcription factors, such as *MYC*; and numerous changes to the immune system[40, 43]. The shift from MGUS and SMM to active MM is extremely complex, multiple stages of transformations are undergone and the genetic landscape changes considerably over the course of the disease.

1.3.6 Treatment of MM

Multiple myeloma may be an incurable disease, however it is treatable. In fact, in the last decade median survival time for newly diagnosed MM patients has almost doubled[3]. Novel therapeutic advances have contributed to this improvement (Table 1.1). Myeloma is usually treated with a combination of drugs, often comprising a corticosteroid, a proteasome inhibitor, and an immunomodulatory drug (IMiD). A common regimen, approved in the USA, European Union and UK for untreated myeloma is the triplet VRd regimen. This consists of the proteasome inhibitor bortezomib (brand name Velcade), the IMiD lenalidomide (brand name Revlimid), and the corticosteroid dexamethasone. More commonly in the UK (via the NHS), bortezomib (Velcade), thalidomide and dexamethasone (known as VTd) is used as an initial treatment for MM. Recently, the regimen DVTd has been introduced in the UK, which is the above triplet combined with the anti-CD38 monoclonal antibody daratumumab (Darzalex). DVTd has been shown to improve progression-free survival and response rates in MM patients compared to VTd. Additionally, any MM patients who are eligible (based on frailty, age, organ function and comorbidities) receive high-dose chemotherapy followed by autologous stem cell transplantation (HDT-ASCT) as standard treatment.

Year	Treatment	Usage	Ref
1958	Melphalan	An alkylating agent, first used in MM in 1958.	[44]
1960s	Corticosteroids	Prednisone trialled in MM. Combination of prednisone and melphalan showed an increased survival over melphalan alone. Dexamethasone and prednisone have become standard treatment in MM.	[45, 46]
1980s	Stem-cell transplants	Successful transplantations in patients with MM. MM patient gets high-dose chemotherapy to kill cells in the BM and then receives new, healthy stem cells. Autologous (patient's own stem cells) transplants are standard treatment for any eligible patients. Allogenic (another person's stem cells) transplants are riskier, more toxic and not standard in clinical practice.	[47–51]
2003	Proteasome inhibitors	First-in-class PI, Bortezomib (BTZ), was approved for use in RRMM and later (2008) for naive patients. Carfilzomib (CFZ) was approved in 2012 for advanced MM and in 2015 for treatment of relapsed MM. The oral PI, ixazomib, was approved as a combination treatment with lenalidomide and dexamethasone in 2016 for people who have received at least one previous treatment.	[52–54]
2006	IMiDs	The anti-tumour activity of thalidomide was demonstrated in 1999, this led to the development of lenalidomide, the first approved immunomodulatory imide drug (IMiD) for use in MM. Currently, thalidomide, lenalidomide and pomalidomide are approved for use in MM.	[55–57]
2015	Monoclonal antibodies	Daratumumab, isatuximab (both anti-CD38) and elotuzumab (anti-SLAMF7; not approved in the UK) monoclonal antibodies approved for use in MM.	[58, 59]
2020	Antibody-drug conjugates	In 2020, Belantamab mafodotin-blmf (Blenrep), was approved by the FDA for use in MM patients who have already received 4 other treatments. Blenrep is an anti-BCMA monoclonal antibody linked to a chemotherapy drug.	[60, 61]
2020	Nuclear export inhibitors	In 2020, Selinexor was approved by the FDA for use in combination with BTZ and dexamethasone for MM patients who have had at least one prior therapy (not approved in the UK).	[62, 63]

Table 1.1: Timeline of treatment options for multiple myeloma (MM). Listed by first usage or approval for MM in any country. USA FDA approved drugs not all approved yet in the UK. PI= proteasome inhibitor, BM= bone marrow, RRMM= relapsed and refractory MM.

Proteasome inhibitors

Proteasome inhibitors have contributed greatly to the improved prognosis of MM since their introduction into treatment regimes. The first-in-class proteasome inhibitor bortezomib (Velcade; BTZ) was approved by the FDA in 2003 as a single-agent for injection of relapsed MM[52]. Since then it has been approved for use in combination therapies. Bortezomib in combination with melphalan-prednisone proved to be superior to the previous standard of care for patients ineligible for HDT-ASCT of melphalan-prednisone alone, increasing progression free survival[64]. The combination of bortezomib, dexamethasone and thalidomide was also shown to be superior to previous standard of care for patients prior to ASCT[65]. In 2010, bortezomib was approved as a frontline therapy for treatment-naive MM patients. Since then, two more proteasome inhibitors have been approved, carfilzomib (CFZ) and ixazomib. Carfilzomib is structurally and mechanistically different to bortezomib and shows activity on bortezomib resistant primary MM cells[65]; it is approved for relapsed or refractory MM. Additionally, CFZ and BTZ have different side effect profiles. BTZ treatment displays side effects such as peripheral neuropathy (PNP). PNP has been reported in up to 30% of MM patients treated with BTZ-based regimens[66]. CFZ treatment has lower rates of PNP, however is associated with significant incidence of cardiovascular adverse events (heart failure, hypertension, ischemia, and arrhythmias)[67]. In relapsed MM patients, treatment choice often depends on prior therapy, recorded comorbidities and side effect profiles of the patient.

The ubiquitin-proteasome system

Proteasome inhibitors work by blocking the action of the proteasome in the cell. Misfolded proteins can be harmful to a cell, so the combined activity of molecular chaperones, which aid in protein folding, and the ubiquitin-proteasome system (UPS), which acts to digest misfolded proteins, is needed to prevent aberrant protein aggregation. Unneeded, misfolded or damaged proteins are tagged with lysine-48-linked poly-ubiquitin chains, marking them for degradation by the proteasome

(Figure 1.5a). The proteasome is described as a complex ‘protein destruction machine’. The proteasome consists of a 20S core particle, a central hollow cylinder, and 19S regulatory caps associated with each end of the cylinder. The 19S regulatory caps perform substrate recognition, deubiquitination, unfolding and threading of the protein substrate into the 20S core. The core is made up of four stacked heptameric ring structures. The outer rings are responsible for docking to the 19S cap and for acting as a gate to the inner rings. The inner rings consist of seven β subunits, containing inward-facing protease active sites for degrading proteins[68, 69] (Figures 1.5a and 1.5b).

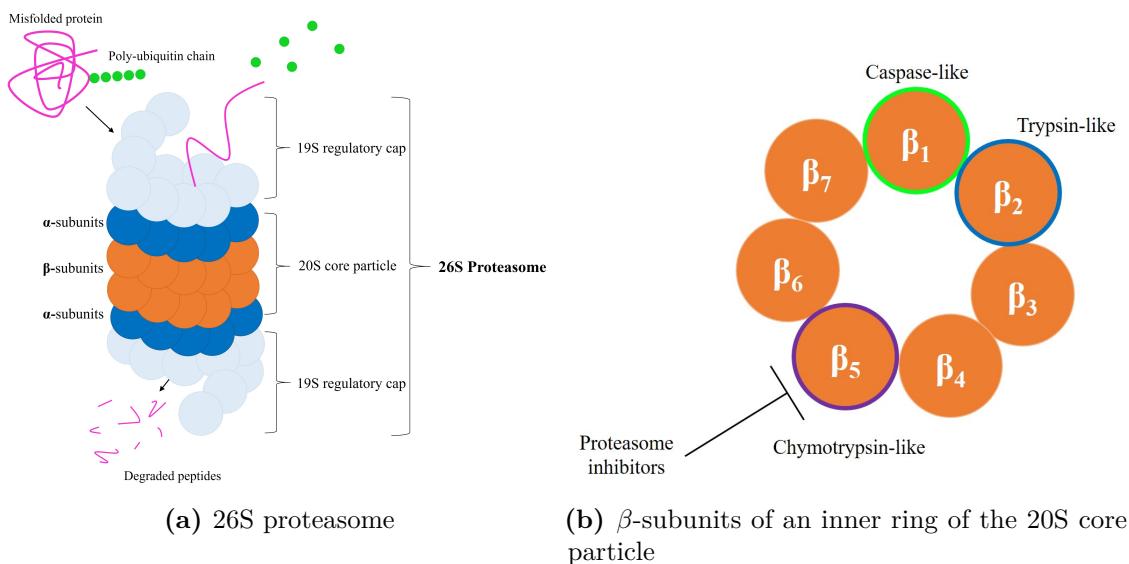

Figure 1.5: Structure of the proteasome. a) The structure of the 26S proteasome, comprised of the 19S regulatory caps and 20S core particle. A misfolded protein tagged with a poly-ubiquitin chain is recognised by the 19S regulatory cap, which cleaves the ubiquitins from the protein and threads the protein through to the core, where it is degraded into small peptides. The 20S core particle is made up of two outer rings of α -subunits and two inner rings of β -subunits. b) The β -subunit arrangement of an inner ring of the 20S particle. β_1 (caspase-like), β_2 (trypsin-like) and β_5 (chymotrypsin-like) are the proteolytically active subunits. Proteasome inhibitors are designed to primarily inhibit β_5 subunits.

PI mechanism of action

Of the seven proteasome β subunits, only β_1 , β_3 and β_5 are proteolytically active (Figure 1.5b). PIs are designed to target β_5 as it has been shown as the rate limiting protease for proteasomal protein turnover[70]. Bortezomib reversibly co-inhibits β_5

and $\beta 1$ subunits, whilst carfilzomib irreversibly binds to $\beta 5$, with greater selectivity than bortezomib, and at higher doses binds to $\beta 2$ as well[70].

The precise downstream effects of β subunit proteasome inhibition are not fully understood, however the unfolded protein response (UPR), NF- κ B signalling, JNK signalling, apoptotic factors and p53 are thought to be involved in the anti-MM effects[71]. Specifically, the action of the UPR has been demonstrated as an important mechanism in the anti-MM effect of PIs. MM cells secrete large amounts of monoclonal protein, leading to the rapid accumulation of misfolded proteins within the endoplasmic-reticulum (ER) lumen. This results in heightened ER stress, which is compensated by the UPR by reducing global protein translation and up-regulating UPS machinery[72]. Therefore, by inhibiting the proteasome, fewer ubiquitin-tagged proteins are degraded and more misfolded proteins accumulate in the ER lumen. ER stress is then further increased, causing the UPR to switch from a homeostatic, pro-survival system to a pro-apoptotic pathway[71, 72].

Another important mechanism for PI activity is the attenuation of NF- κ B signalling. I κ B α , a specific endogenous inhibitor of the transcription factor NF κ B, is a protein degraded by the proteasome. Inhibition of the proteasome increases levels of I κ B α , thereby abolishing NF κ B signalling. NF κ B is a key transcription factor in many cancers, contributing to overall tumour growth and chemoresistance. NF κ B has been shown to promote tumour cell proliferation, anti-apoptotic and angiogenic factors[73].

1.3.7 Drug resistance in MM

Although the standard therapeutics are effective at killing MM cells initially, long-term treatment inevitably results in a drug-resistant relapse. Drug resistance is one of the biggest barriers in the treatment of MM, as in many other cancers. Patients follow a pattern of peaks and troughs of treatment cycles, remission and relapse, until all therapies have little effect (Figure 1.6).

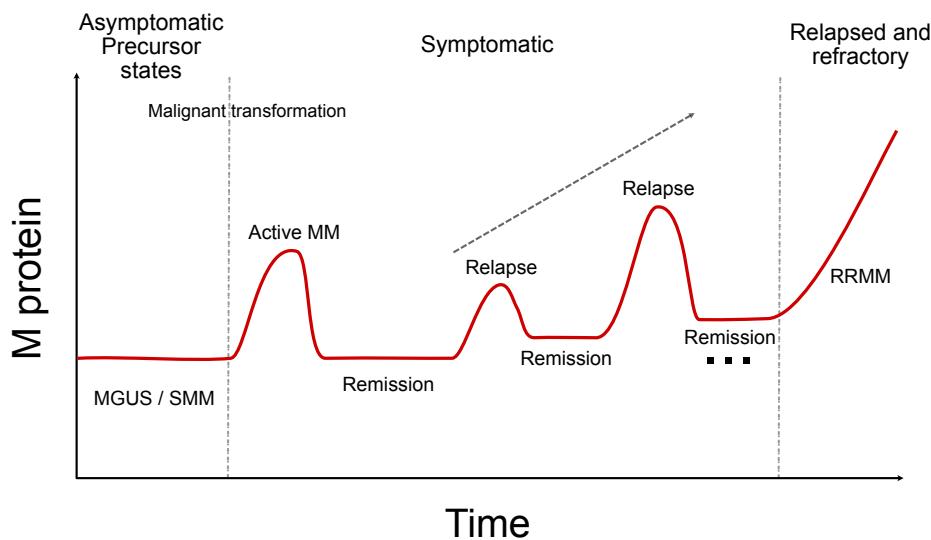

Figure 1.6: MM treatment cycles and disease progression over time. All MM patients begin with precursor states monoclonal gammopathy of unknown significance (MGUS) and/or smouldering multiple myeloma (SMM) prior to a malignant transformation to symptomatic/active MM. Patients undergo cycles of treatment, remission and relapse until eventually becoming relapsed and refractory (RRMM) and no longer responsive to treatment.

Minimal residual disease

Minimal residual disease (MRD) is when a small number of cancer cells remain in the body after treatment. These surviving cells are often undetectable and cause no symptoms, but they have the potential to proliferate and cause patients to relapse. MRD status after treatment is used as a prognostic factor and a marker of therapeutic success. Persistent MRD after a treatment cycle indicates that many MM cells were not killed and the patient is expected to relapse in the near future[74]. Clinical MRD negativity is defined as no cancer cells being detected in the background of at least 10^5 normal cells by multi-parameteric flow cytometry (MFC) or next-generation sequencing (NGS) technology in MM patients who have achieved complete remission (CR)[75]. Many studies have shown MRD negativity is positively associated with prolonged progression-free survival (PFS) and overall-survival (OS) in MM[76–78].

Clonal evolution

MM was originally thought to follow a linear pattern of evolution over time, however MM actually displays clonal evolution and intra-clonal heterogeneity, similar to ‘Darwinian’ natural selection: individual clones compete for the same microenvironmental ‘niche’ and limited resources, with anti-MM therapies acting as environmental selective pressure. Three seminal papers from 2012 elucidated the clonal element of MM disease progression using time-course analyses of primary MM samples[79–81]. These studies revealed substantial heterogeneity within tumour clones from the same patient (intra-patient heterogeneity). Egan et al. (2012) collected DNA from a single MM patient over a five-year period, covering their initial diagnosis, first relapse, second relapse, and end-stage secondary plasma cell leukemia, and performed whole genome sequencing (WGS) on the samples[79]. The group observed genomic sequence variants that were only detectable at alternating time points, suggesting the ‘waxing and waning’ of different independent clones over time and treatment-courses, which rose and fell in dominance[79]. Walker et al. (2012) further corroborated this finding and demonstrated intra-patient heterogeneity by identifying clonal and subclonal RAS mutations using whole exome sequencing (WES); this was also confirmed at the single-cell level[81]. It has since been shown that intra-patient heterogeneity is present at premalignant phases of MM (MGUS and SMM). On average, three to six major subclones are uniformly present at each stage of MM[82], although, this still might be a conservative estimate. MM bone marrow aspirates are taken from a single site, usually the back of the hip bone. Spatial genomic heterogeneity within MM, means there are probably far greater than six subclones present in a MM patient at one time, distributed across the whole body[83].

Keats et al. (2012) described three distinct patterns for clonal evolution in MM: stable, linear evolution, and heterogeneous clonal mixtures with shifting predominant clones (branching evolution)[80]. For clonally stable myeloma, there are fewer mutations over the disease course; for linear evolution, new genetic

aberrations are gained on top of existing mutations; whereas in branching evolution new clones with a new set of genetic aberrations appear over time.

Figure 1.7: Minimal residual disease (MRD) and clonal evolution of MM following treatment. a) Initial treatment of newly-diagnosed MM kills the majority of MM clones (sensitive subclones), resistant subclones survive and proliferate. Pre-existing resistant subclones and new subclones form which are resistant to subsequent treatments, until MM patients are relapsed and refractory. b) Clonal evolution of MM following treatment, leading to a complete response- which gives rise to mainly branching evolution, and a partial response, which gives more stable clonal patterns. Figure adapted from[84].

Drug treatment plays an important role in clonal evolution. Therapeutics place selective pressure on the MM clonal architecture, whereby more sensitive clones are completely eradicated by drug treatment and only highly-malignant drug-resistant clones remain, outcompeting other clones[82] (Figure 1.7a). These resistant clones are thought to affect the rate of disease progression and cause relapse of MM. Clonal evolution and diversity are causes of acquired drug resistance in MM. Moreover, anti-MM therapy response effectiveness has been shown to affect the pattern of clonal evolution. Jones et al. (2019) demonstrated that patients achieving a CR to treatment followed branching and linear evolution patterns, whilst patients with a partial response to treatment sometimes maintained a more stable subclonal structure[84] (Figure 1.7b). By the time patients are multi-drug refractory, almost all MM patients have a branching and complex clonal structure[85].

The clonal heterogeneity seen in MM makes treatment complex. Each individual clone has potentially different clinical behaviour, for example some clones will be more proliferative than others, and associated with an early relapse. Additionally, some clones may have different sensitivity to specific therapies compared to other

clones. This highlights the rationale of using a combinatorial approach for treatment. Some agents may be more effective on certain subclones than others, and other agents more effective on other subclones. Therefore, agents are combined to try and achieve a deeper treatment response and reduce residual disease. However, this approach also means that the clones that remain are more likely to be the most resistant clones, capable of surviving a triplet combination of drugs. Combining a higher number of drugs could result in a more complete remission, however the added toxicity of the agents limits this. Ideally, clonal dominance would be assessed after each relapse, as the dominance of clones is constantly changing. Agents that were effective in a previous treatment cycle may become effective again, if the resistant clone has become less dominant in the balance of clones[86]. However, in practice, this is rarely performed, as sequencing is not yet mainstream enough to be routine in the clinic.

Overcoming drug resistance

The molecular mechanisms underlying drug resistance development need to be better understood for standard MM treatments. This will aid in the design of novel therapies and inform better use of existing therapies. Previous studies on proteasome drug resistance have been performed and certain mechanisms and genes have been identified. For example, point mutations have been noted in the *PSMB5* gene (coding for the β 5 subunit of the proteasome), as well as over-expression of the β 5 subunit[87]. Other upregulated genes have been identified, for example *ABCB1*, coding for P-glycoprotein, responsible for pumping various substrates out of the cell, also referred to as multidrug resistant protein 1. *XBP1*, involved in the UPR, has been seen to be downregulated in PI resistance[87]. Although many genes have been identified to be differentially expressed in drug resistant MM, the mechanism is not fully elucidated and further research is imperative in the progression of MM treatment.

Another avenue to improve MM survival, would be to identify novel therapeutics effective against MM, which are capable of overcoming acquired anti-cancer drug resistance. By increasing the arsenal of drugs available to treat MM, the time until

patients become refractory and no longer respond to treatment could be prolonged. Therapeutics with a novel mechanism of action are likely to be more effective for MM patients who have undergone several treatment cycles than drugs belonging to the same class as drugs they have previously been treated with. Novel therapeutics would have less overlap of mechanism of action with existing drugs, therefore there would be less cross-resistance. However, MM typically affects elderly people and after exposure to numerous rounds of treatment cycles, often relapsed and refractory MM (RRMM) patients are more frail and have more suppressed bone marrows. Therefore, it is important for therapies that are intended to treat RRMM patients are tolerable and not excessively immunosuppressive for patients.

A future aim for the treatment of MM is to implement a personalised, targeted approach to an individual patient's MM in the clinic. In theory, this would be achieved by characterising a patient's clonal architecture using NGS technologies, and then predicting the most effective treatment strategy for the individual. This could be achieved by targeting a highly conserved mutation (early in branching events) or a mutation of a specifically resistant/malignant clone, or by assessing many other factors. For example, the Horizon 2020 project aims to clinically validate MMPredict, a microarray-test that can genetic subtype MM patients and predict their treatment response based on gene-expression profiling[88]. The inter- and intra-patient heterogeneity seen in MM could make it a very promising candidate for personalised medicine. Although, due to the very nature of MM's genomic instability and ability to evolve resistance, targeting only one subclone or genetic variant is likely to fail. Personalised patient treatment is quite far away from the clinic in MM, but the prospect is quite exciting.

1.4 Transcriptomics, proteomics and epigenomics

It has been shown that changes in the genome, transcriptome, epigenome and proteome all contribute to disease progression and drug resistance in MM. Therefore, to sufficiently investigate the multiple layers driving MM and to assess the effectiveness of new therapeutics, a multi-omics approach must be employed.

1.4.1 DNA and the genome

The genome is the genetic material of an organism, it consists of deoxyribonucleic acid (DNA). DNA consists of two polynucleotide chains (or strands), running anti-parallel to each other, held together in a double helix structure by hydrogen bonds. Nucleotides are composed of a five-carbon sugar (deoxyribose for DNA), attached to one or more phosphate groups (a single phosphate group in the case of DNA) and a nitrogenous base. Nucleotides are covalently linked to form an alternating sugar-phosphate backbone, with bases extending from each sugar towards the inside of the double helix. Nucleotides contain four different types of bases: adenine (A), cytosine (C), guanine (G) and thymine (T). The two DNA chains are held together by hydrogen bonds via complementary base pairing between the bases of the strands, A pairing with T and G pairing with C. Often sections of DNA are denoted as their sequence of A, C, T and Gs (in order reading from the 5' to 3' direction).

Every individual has approximately 6 billion base pairs of DNA per cell, which would amount to about 2 metres of DNA if laid end-to-end. The nucleus of a human cell is approximately 6 μm in diameter, therefore chromosomal DNA must be folded tightly to fit. DNA packaging is a complex task involving numerous specialised proteins. Negatively charged DNA is complexed with an octomer of positively charged proteins called histones to form nucleosomes. The histone core is made up of eight subunits, two copies of H2A, H2B, H3 and H4 subunits. DNA wraps tightly around the histone core 1.65 times. Linker DNA connects adjacent nucleosomes, to resemble ‘beads on a string’. Nucleosomes fold tightly to form 30nm chromatin fibre, which in turns forms loops averaging 300nm in length. This fibre is folded and compressed again to form fiber 250nm in width with loops of 700nm in length. Tight coiling of this fiber forms the single chromatids of chromosomes[89, 90]. Human cells contain 23 pairs of chromosomes.

The complete genome is made up of coding DNA (genes), non-coding DNA, as well as mitochondrial DNA and ribosomal DNA. An alteration in the nucleotide sequence of the genome is called a mutation. There are a number of types of mutations, including insertions, deletions, inversions, substitutions and duplications.

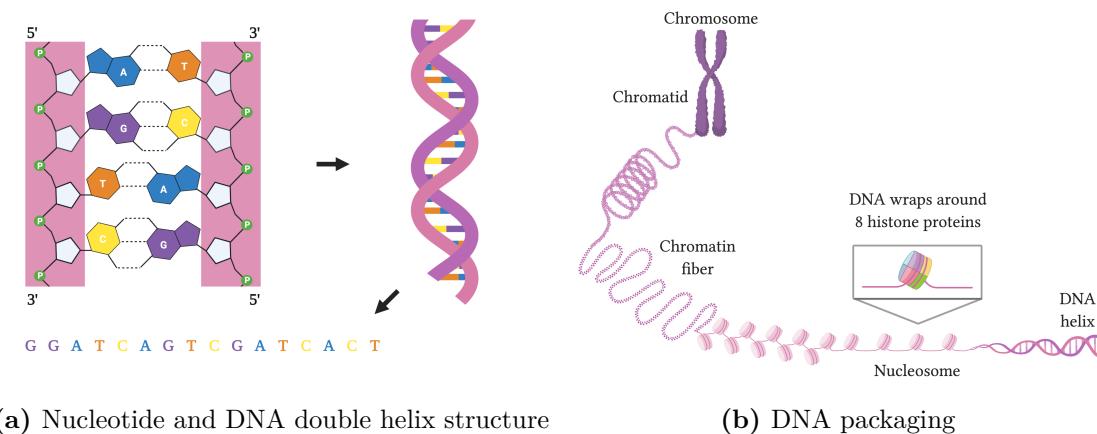

Figure 1.8: a) Deoxyribonucleic acid (DNA) nucleotides and double helix structure. DNA consists of two polynucleotide chains. Nucleotides are covalently linked to one another, forming a sugar-phosphate backbone. They contain one of four bases adenine (A), cytosine (C), guanine (G) and thymine (T). DNA strands are held together by hydrogen bonds between complementary base pairs, A pairing with T and G pairing with C. Sections of DNA are often read by their sequence of bases from the 5' direction to the 3' direction. b) Chromosomal DNA packaging in the cell. DNA wraps 1.65 times around an octamer of histone proteins, to form a structure called a nucleosome. Nucleosomes are linked by linker DNA to form a structure that resembles ‘beads on a string’. Nucleosomes fold to create chromatin fiber. This in turn forms loops and coils tighter and tighter until it makes up the single chromatids of chromosomes.

A technique called whole genome sequencing (WGS) can be used to determine the sequence of nucleotides in an individual’s DNA and therefore it can be used to determine any variations in the genome.

1.4.2 The epigenome

Epigenetics is the study of any heritable phenotypic changes that do not involve alterations of the DNA sequence itself. These changes occur at the chromatin level. Epigenetic changes include histone modifications, DNA methylation and chromatin remodelling.

DNA methylation is the addition of methyl groups to the C5 position of cytosines in DNA. This happens extensively at CpG sites (cytosine followed by a guanine). Stretches of DNA with a high CpG ratio (CpG islands) are often found in the promoter region of genes. Increased DNA methylation at CpG islands results in transcriptional silencing of those genes. Genome wide DNA methylation is often

examined using DNA-methylation-seq or DNA methylation microarrays.

DNA wraps tightly around histones (Section 1.4.1), they contribute to the tight packaging of DNA. Histone modifications are post-translational modifications. They include methylation, acetylation, phosphorylation, ubiquitination and sumoylation. Histone modifications affect transcriptional activity either by directly influencing the structure of chromatin and DNA accessibility or by regulating binding of effector molecules to ‘read’ histone marks to mediate downstream biological effects. Histone modifications also regulate DNA processes, such as repair, replication and recombination[91]. Chromatin immunoprecipitation sequencing (ChIP-seq) can be used to investigate and measure various post-translational histone modifications.

Chromatin remodelling is the process of modifying chromatin architecture to regulate the accessibility of DNA. Gene expression is regulated by allowing certain gene regions better access to the transcription machinery. This is achieved by ATP-dependent chromatin-remodelling complexes moving, ejecting or restructuring nucleosomes. Assay for transposase-accessible chromatin sequencing (ATAC-seq) can be used to identify accessible DNA regions.

1.4.3 The transcriptome

Transcription is the first of many steps in gene expression. During transcription, the enzyme RNA polymerase reads a DNA sequence and produces an anti-parallel, complementary ribonucleic acid (RNA) strand. The transcriptome is the set of all RNA transcripts of an individual. RNA is a nucleic acid similar to DNA. Like DNA it has a sugar-phosphate backbone and 4 different types of bases attached to each sugar. However, unlike DNA, RNA is single-stranded, it contains the sugar ribose in place of deoxyribose, and the nucleotide uracil (U) in place of thymine (T).

Despite the chemical differences between DNA and RNA, they are essentially written in the ‘same language’ and one-to-one mapping of nucleotides can be achieved. Transcription begins with the unwinding and opening of a small part of the DNA double helix, so bases are exposed. One strand of DNA acts as a template and the RNA chain is formed by complementary base pairing with the

template. RNA polymerases catalyse the reaction of forming phosphodiester bonds between nucleotides, forming the RNA chain. The RNA polymerase moves stepwise along the DNA chain, unwinding the chain just ahead exposing a new region of the template strand. Just behind the region where ribonucleotides are being added, the DNA helix reforms.

The genes in a cell's DNA that specify the amino acid sequence and result in protein synthesis are called messenger RNA (mRNA) molecules. Genes that produce the RNA molecule itself are called non-coding RNAs, because they do not code for proteins. There are many other types of RNA, such as transfer RNA (tRNA), ribosomal RNA (rRNA) and micro RNA (miRNA).

Traditionally microarrays were used to measure gene expression. Now RNA-seq (outlined in section 1.4.6) is more commonly used to study gene expression and the transcriptome. Depending on the library preparation, different types of RNAs can be selected for or excluded, to study different RNA molecules.

1.4.4 mRNA translation

The proteome is the entire set of proteins that is or can be expressed by an organism. mRNAs are translated into protein molecules. mRNA is made up of only four different nucleotides, but proteins are made up of 20 amino acids, therefore a direct one-to-one function matching nucleotides to amino acids is impossible. Instead, the sequence of mRNA is read in groups of three consecutive nucleotides, called a codon. The three positions of a codon, and each position with four possible base options (A, C, U and G), gives a total of 64 different permutations (i.e. 4^3). Therefore, some combinations map to the same amino acid (many-to-one function), or signal to terminate translation of the current protein (known as a stop codon). This genetic code directs the translation from mRNA to protein. To ensure accuracy, translation takes place in the ribosome. The ribosome is a complex macromolecular catalytic machine with one large and one small subunit, made up of ribosomal RNAs (rRNAs) and more than 50 different ribosomal proteins[69]. Eukaryotic cells contain millions of ribosomes in their cytoplasm.

Codons on mRNA do not directly recognize their given amino acid, they require tRNA molecules that bind to both the codon on mRNA and the correct amino acid. tRNAs possess an anticodon, a set of three nucleotides complementary to a given codon. Firstly, tRNAs are coupled to their cognate amino acid. This reaction is catalysed by aminoacyl-tRNA synthetase (aaRS) enzymes. aaRSs attach amino acids to the 3' end of tRNA. Most cells have a specific aaRS for each amino acid. Once the tRNA is charged with the correct amino acid, the tRNA molecule binds to its complementary codon on mRNA during protein synthesis at the ribosome. Subsequent aminoacylated tRNA molecules bind to mRNA codons. A polypeptide chain grows by stepwise addition of amino acid to the C-terminal end. The formation of the new peptide bond between amino acids releases the tRNA molecule. The large and small subunits of the ribosome then translocate, shifting the reading frame by three nucleotides on the mRNA. The peptide chain grows until a stop codon is reached and synthesis of the current protein is complete[69].

Protein translation is partly regulated by availability of mRNAs, but it also depends on other factors such as RNA silencing and post-transcriptional modifications. Proteins have a large array of functions, such as transporting small molecules, catalysing reactions, cell-cell signalling and providing structural support.

Proteomics is the study of the proteome. CyTOF and LC-MS/MS are techniques often employed to examine the proteome.

1.4.5 Sequencing

DNA is often referred to as the ‘genetic master code’, therefore the ability to decode the order of nucleic acids has been seen as a highly desirable feat since its discovery. Sequencing is the process of determining the sequence of nucleotides of nucleic acid residues. Over the last half-century, large numbers of researchers and vast sums of money have been applied to facilitate the techniques and technologies to decode DNA and RNA molecules’ nucleotide sequence[92]. Over this time, massive technological innovations have been developed. The most commonly used ‘first-generation’ DNA-sequencing technology, Sanger sequencing, was developed in 1977[93]. Sanger

sequencing or the ‘chain termination method’, utilised radiolabelled partially digested fragments. For Sanger sequencing performed at present (the polymerase chain reaction [PCR] was not invented until 1985), chain-termination PCR is performed with a mix of regular nucleotides (deoxynucleotide triphosphates; dNTPs) and fluorescently-or radiolabelled, chain-terminating dNTPs (dideoxynucleotide triphosphates; ddNTPs), using the DNA of interest as a template. During the extension step of PCR, when DNA polymerase incorporates a ddNTP randomly, extension ceases. This creates greater than a million copies of the DNA sequence of interest, all terminated at random lengths by the ddNTPs. Capillary electrophoresis is then used to separate the extension products by size. The gel is then read to determine the sequence. By reading the gel bands from smallest to largest, the 5' to 3' sequence of the original DNA strand can be inferred. Sanger sequencing was used by the Human Genome Project, an international research effort to determine the DNA sequence of the entire human genome[94]. The whole project took approximately 13 years to complete, and was reported to have cost \$3 billion.

Sanger sequencing dominated the sequencing world for over 30 years, until the advent of ‘next-generation sequencing’ (NGS; now being dubbed ‘second-generation sequencing’, with the advent of newer technologies). NGS differs from its predecessors in that it is highly scalable and massively parallel. Using NGS, one can rapidly sequence the entire human genome in one day, for approximately \$5000. It is quicker and cheaper than traditional Sanger sequencing, and has progressed data output from the kilobase range up to potentially multiple terabases per run. Today, the largest and most commonly used NGS sequencing technology platform is Illumina, who own around 80% of the global sequencing market. NGS can be used to study the transcriptome, using RNA-seq techniques (Section 1.4.6); the epigenome, using techniques such as ChIP-seq or ATAC-seq; or the genome using techniques such as whole genome sequencing (WGS).

Recently, long-read technologies are becoming more prominent in the sequencing field. Illumina short-read sequencing limits read length to between 50 and 300 base pairs (bp). This read length is too short to detect more than 70% of human genome

structural variation. Moreover, some of the most mutation-prone regions of the genome are inaccessible due to repetitive sequences or GC-rich content, limiting sequence coverage and leaving large regions of the genome critically understudied[95]. Long-read technologies are capable of generating continuous sequences ranging from 10 kilobases to several megabases, enabling the sequencing of full-length transcripts. The two main emerging long-read technologies are PacBio single-molecule real-time (SMRT) sequencing[96] and Oxford Nanopore Technologies (ONT) sequencing[97, 98], together marking the birth of ‘third-generation sequencing’ (TGS). Both PacBio and ONT sequencing sequence single DNA molecules, rather than a pool of PCR-amplified fragments. PacBio sequencing employs a sequencing-by-synthesis strategy (similar to Illumina sequencing), with circular DNA templates to improve accuracy. ONT sequences a native linear single-stranded DNA molecule by measuring current changes as bases are threaded through a nanopore[99]. Whilst TGS technologies have the advantage of longer read length, the methods are also plagued by higher base-calling error rates and lower throughput than NGS technologies[99, 100]. Therefore, this makes applying TGS to single-cell RNA-seq especially challenging. Due to the lower through-put, fewer cells can be reported on at a comparable read-depth to NGS technologies; and due to the high base-calling error rate, inaccurate cellular and molecular barcode assignment can complicate associating mRNA reads with their cell of origin.

1.4.6 RNA-seq

Most modern RNA sequencing (RNA-seq) implements NGS technology to analyse RNA across the transcriptome of a biological sample and allows for the quantification of gene expression.

Bulk RNA-seq

Bulk RNA-seq measures the average expression across a sample. Creating a bulk RNA-seq library involves isolating RNA from a biological sample, filtering for a specific type of RNA (most commonly mRNA), fragmentation of RNA into

fragments, reverse transcription of the fragments to generate a complementary DNA (cDNA) library, end repair and adaptor ligation of the cDNA library, followed by PCR amplification ready for sequencing.

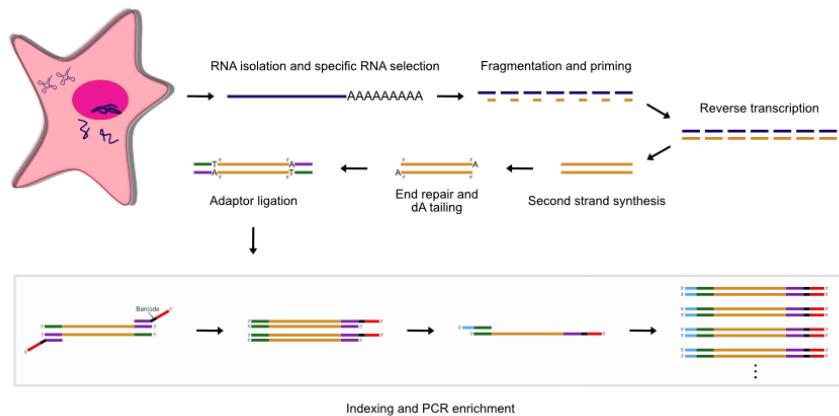

Figure 1.9: Outline of bulk RNA-seq library prep. Cells are lysed and RNA is extracted. The specific RNA of interest is selected and enriched, for example selecting for mRNA using polyA selection or ribo-depletion. The mRNA is fragmented into smaller pieces of RNA. First and second stranded cDNA are reverse transcribed from the RNA fragments using random primers. The ends of the cDNA are repaired and dAMP (dA) tails are added to the 3' end of the DNA. Adaptors are ligated to the 3' and 5' end of the cDNA. These adaptors contain complementary sequences that allow the fragments to hybridize to the flow cell during sequencing. Universal (P5/i5) and index (P7/i7) primers are added to the adaptor ligated DNA. The libraries are then amplified using PCR and cleaned-up, ready for sequencing.

Single-cell RNA-seq

Single-cell RNA-seq (scRNA-seq) measures gene expression for each individual cell across a population of cells and therefore provides information on clonal diversity that may be lost when pooling cells into bulk samples. Since its inception in 2009[101], there have been numerous scRNA-seq techniques developed, such as SMART-seq2[102], Drop-seq[103], STRT[104], scCOLOR-seq[100] and inDrops[105]. scRNA-seq library preparation shares many steps with bulk RNA-seq workflow, however preliminary steps are required to isolate single cells and to barcode reads that originated from each given cell. For droplet-based scRNA-seq (dscRNA-seq) methods, single cells are isolated using microfluidic devices by individually encapsulating

them in aqueous droplets contained in oil. Drop-Seq, a dscRNA-seq method, is outlined in Figure 1.10.

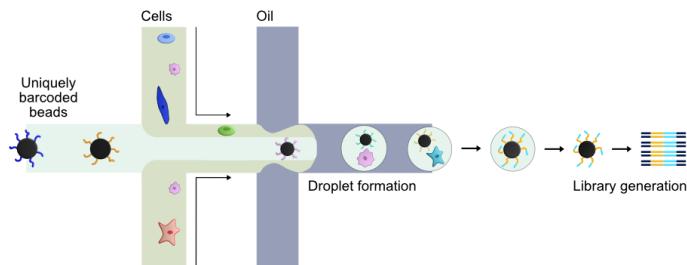

Figure 1.10: Outline of Drop-Seq, a droplet-based scRNA-seq method. A microfluidic device combines two aqueous flows, one containing cells and the other containing barcoded primer beads suspended in lysis buffer. The two aqueous channels flow across an oil channel to form aqueous droplets surrounded by oil. Few droplets contain both a cell and a bead (to avoid doublets, whereby droplets contain two or more cells). Following droplet formation, the cell is lysed and its mRNAs are released, which then hybridise to the primers on the bead surface. A reagent is added to break up the droplets and the beads are collected and washed. The mRNAs are reverse-transcribed into cDNAs, generating a set of “STAMPS” (single-cell transcriptomes attached to microparticles) and template switching is used to introduce a PCR handle. The barcoded STAMPS can then be amplified using PCR.

1.5 Thesis aims and chapter outline

This thesis aims to identify novel therapeutics with anti-MM properties, capable of overcoming acquired drug resistance in MM.

Chapter 1: General introduction of the adaptive immune system, multiple myeloma (MM) and treatment of MM, as well as an introduction into the multiple layers of information underpinning life: the genome, transcriptome, epigenome and proteome, and the different multi-omic techniques that can be employed to investigate them.

Chapter 2: Literature review introducing aminoacyl-tRNA synthetases (aaRS), the roles they play in disease and therapeutics targeting aaRSs, focusing on the prolyl-tRNA synthetase inhibitor, halofuginone (HF) and its applications, particularly in MM.

Chapter 3: Experimental materials and methodology used in this work.

Chapter 4: Outline of computational methods generated to support experimental work and benchmark validations of their effectiveness.

Chapter 5: Investigation of the use of ProRS inhibitors in PI-sensitive and PI-resistant MM cell lines. Bulk RNA-seq is employed and the transcriptional landscape following ProRS inhibitor treatment and ProRS inhibitor resistance is characterised.

Chapter 6: Exploration of ProRS inhibitor treatment of primary BM samples from MM patients at the single cell level. Their effectiveness against newly-diagnosed and relapsed MM patient tissue is investigated.

2

Literature review: aminoacyl-tRNA synthetases and halofuginone

2.1 Introduction

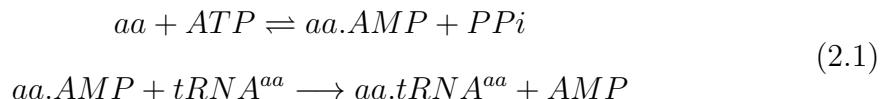

Aminoacyl-tRNA synthetases (aaRS) are a highly-conserved family of enzymes, responsible for “charging” tRNAs with their cognate amino acid[106]. Human cytoplasmic aaRSs are either “free” as individual species or bound in a macromolecular complex, comprised of eight aaRSs and three auxiliary proteins, known as the multi-tRNA synthetase complex (MSC)[106]. On top of their canonical enzymatic role, aaRSs also engage in non-enzymatic functions in numerous pathways, including angiogenesis, inflammation and metabolism. Often species are released from the MSC to regulate these non-canonical activities[107]. aaRSs are involved in numerous diseases, including cancer. Initially, due to their high fidelity and complex evolution over millennia, aaRSs were seen as an attractive drug target for antimicrobials, to enable specifically targeting microbial aaRSs with minimal effects on human cells. The mechanism of action of febrifugine (FF), a quinazoline alkaloid that has long been used as an antimalarial remedy in Chinese medicine, has recently been revealed; it acts as a competitive inhibitor of ProRS (part of the bifunctional glutamyl-prolyl-tRNA synthetase enzyme; EPRS), responsible for charging tRNA^{pro} with proline. Although it has potent antimalarial effects, FF exhibits liver and gastrointestinal (GI) toxicity, so cannot be used as a widespread drug, therefore several analogues of FF were developed in the hope of minimizing toxicity to

the host's cells. One such analogue, halofuginone (HF) was synthesized and was shown to have the most potent antimalarial properties of all the derivatives, with lower toxicity to the host than FF, but still some liver toxicity and GI side effects remain[108]. Halofuginone has been applied to and showed promise in many other non-parasitic diseases too. It has received orphan drug status for scleroderma and HIV-Related Kaposi's Sarcoma[109]. Recently, halofuginone's application in various cancers has become of great interest, including but not limited to: metastatic brain tumours, bladder carcinomas, prostate cancer, renal carcinomas, hepatocellular carcinomas, lung cancer, breast cancer and multiple myeloma[110–115].

This review will introduce the structure and function of (eukaryotic) aminoacyl-tRNA synthetases, provide an insight into their role in pathology and potential as therapeutic targets. aaRSs inhibitors and their application in disease will be explored, focusing on the usage of the prolyl-tRNA synthetase inhibitor, halofuginone, in multiple myeloma.

2.2 Function and structure of aminoacyl-tRNA synthetases

aaRSs are an ancient family of ubiquitous enzymes, conserved across three major domains of life. They can be traced back prior to the “Last Universal Common Ancestor” (LUCA)[116]. aaRSs are essential for protein biosynthesis, and catalyse the first step in translation (Section 1.4.4). aaRSs catalyse the charging of tRNAs with their cognate amino acid. This is a two-step process. Firstly, aaRSs catalyse the formation of an aminoacyl-adenylate (activated amino acid) from their corresponding amino acid and an ATP molecule, releasing an inorganic pyrophosphate. Next, aaRSs catalyse the reaction between the aminoacyl-adenylate and their cognate tRNA to release an AMP molecule and generate an aminoacyl (charged)-tRNA, ready to be used by the ribosome to decode mRNA (Equation 2.1). An example of this process would be prolyl-tRNA synthetase (abbreviated to ProRS) charging tRNA^{Pro} with proline.

Eukaryotes have 20 cytoplasmic aaRS and 20 nuclear-encoded mitochondrial aaRS. These are localised in distinct cellular compartments. aaRSs are often denoted by their one letter amino acid symbol, followed by ARS and either 1 (indicating they are cytoplasmic) or 2 (indicating they are mitochondrial), for example LARS1 for cytoplasmic Leucyl-tRNA synthetase (LeuRS). This review will focus on cytoplasmic aaRS enzymes. aaRS can be divided into two distinct classes based on the structure of the fold of their catalytic domains. Class I aaRS enzymes are functional monomers that contain a dinucleotide or Rossman fold (RF) of alternating alpha-helices and parallel beta-sheets. This fold is where ATP and amino-acid binding takes place and therefore facilitates the aminoacylation reaction. The active site of class I aaRS is marked by the signature motifs “HIGH” (His-Ile-Gly-His) and “KMSKS” (Lys-Met-Ser-Lys-Ser). Within the first half of the RF the HIGH motif helps to correctly position the adenine base of ATP and interacts with the phosphates. The second K of the KMSKS motif is thought to be involved in stabilising the transition state for the primary step of aminoacylation[117]. Amino acid recognition and binding takes place in the catalytic site when the KMSKS motif is open. The KMSKS loop closes after the aaRS binds ATP and the aminoacyl-adenylate is formed[118].

Class II aaRS enzymes are functional dimers or tetramers with an uncommon catalytic core, comprising seven anti-parallel beta-sheets, flanked by alpha-helices. Class II aaRS enzymes are defined by three conserved sequence motifs. Motif 1 is located at the interface of the dimer and enables oligomerization. Motifs 2 and 3 comprise part of the aminoacylation active site and facilitate amino acid/ ATP binding and adenylate formation. Motif 3 binds ATP, and motif 2 is involved in coupling ATP and the amino acid and then transferring the amino acid to the 3'-tRNA[118]. The distinct active-site structures of class I and II enzymes confer markedly different binding mechanisms for the aminoacylation reaction. For example, class I aaRSs bind the tRNA acceptor stem via the minor groove side and bind ATP in an extended conformation, whilst class II aaRSs bind the tRNA acceptor

stem from the major groove side and bind ATP in a bent conformation. The two classes of aaRSs split the twenty amino acids into two groups. Val, Leu, Ile, Met, Glu, Gln, Trp, Tyr, Arg and Cys are activated by their cognate class I aaRS; and Gly, Pro, Ala, Thr, Ser, Hist, Asp, Asm, Lys and Phe are activated by their cognate class II aaRS. Class I and class II can be further divided into different sub-groups, however that is beyond the scope of this review. The structural diversity of aaRSs is likely attributable to the need to exclude similar non-cognate amino acids and to discriminate the correct tRNA isoacceptor.

Both class I and class II aaRSs are multi-domain proteins- in addition to their catalytic domains, they include other domains such as their anti-codon recognition domain or an editing domain. The editing domain found in some aaRSs is to ensure that the essential step of aminoacylation in protein biosynthesis is as accurate as possible, so incorrect amino acids can be removed from aminoacyl-adenylates or mischarged tRNAs[118]. Theoretically, it was estimated that mistranslation rate should be approximately 1 in 200 for amino acids differing by just a methyl group (such as valine and isoleucine)[119], however in vivo work demonstrated that the error frequency is closer to 3 in 10,000 (approximately 1 in 3000)[120]. This suggested the existence of proof-reading capabilities of aaRSs, to account for the difference between observed and predicted error rates. Editing capability has since been shown to be of high functional importance to some aaRSs. For example, a study in mice in which there was a missense in the editing domain of AlaRS[121]. The impaired proof reading activity of the enzyme lead to an accumulation of misfolded proteins, resulting in the activation of the unfolded protein response and substantial neurodegeneration[121]. Not all aaRSs possess editing activity, only about half do, however the high specificity of the active site of those aaRSs is enough to alleviate proofreading need.

2.2.1 Multi-tRNA synthetase complexes

Higher eukaryotes contain macromolecular complexes, which consist of nine enzymes and three auxiliary proteins, known as multi-tRNA synthetase complexes (MSC).

The 11 cytoplasmic aaRSs not located in the MSC remain free as individual species. The nine cytoplasmic aaRS enzymes of the MSC are GluRS (EARS1), ProRS (PARS1), IsoRS (IARS1), MetRS (MARS1), GlnRS (QARS1), LysRS (KARS1), ArgRS (RARS1), AspRS (DARS1), LeuRS (LARS1). GluRS and ProRS are transcribed from a single gene into one polypeptide chain, connected via triple repeats of WHEP domains to form a bifunctional enzyme, EPRS1. The non-enzyme component of the MSC consists of three aminoacyl-tRNA synthetase-interacting multifunctional proteins (AIMP), AIMP1, AIMP2 and AIMP3. Human MSCs contain more class II aaRS enzymes than other species, namely DARS1, KARS1, and PARS1, they also contain more auxiliary proteins. Human MSC components have several additional domains or motifs (Figure 2.1A), for instance GST-homology domains in EPRS, MetRS, AIMP1 and 2, and WHEP domains in EPRS and MetRS[107, 122, 123].

The structure of human MSC has not been fully elucidated, however some sub MSC-complex structures have been revealed. LysRS forms a homodimer and is anchored to the N-terminal peptide region of AIMP2 within the main body of the MSC. MetRS, AIMP3, EPRS1 and AIMP2 are compactly linked through their GST-homology domains. ArgRS, GlnRS and AIMP1 assemble into a heterotrimeric complex[107, 122, 123]. A proposed bisymmetrical model of the human MSC, via homodimerization of AspRS and ProRS, is shown in Figure 2.1b, based on subcomplex and interaction data[124–126]. This hypothesis proposes that the MSC is a super-complex of two identical, symmetrically arranged subunits (symmetrical along the y-axis in Figure 2.1b), each containing one copy of the constituent elements, except for LysRS which is present as a dimer in each subunit.

The function of the MSC was originally thought to be to increase efficiency of protein biosynthesis by localising aaRSs. Another proposed function of the MSC was to increase stability of its components. It has been shown using systematic depletion analysis that some of the components are in fact intrinsically less stable in isolation and dependent on their neighbours for stability[127]. More recently, examples have emerged where the MSC seems to work as a ‘molecular reservoir’

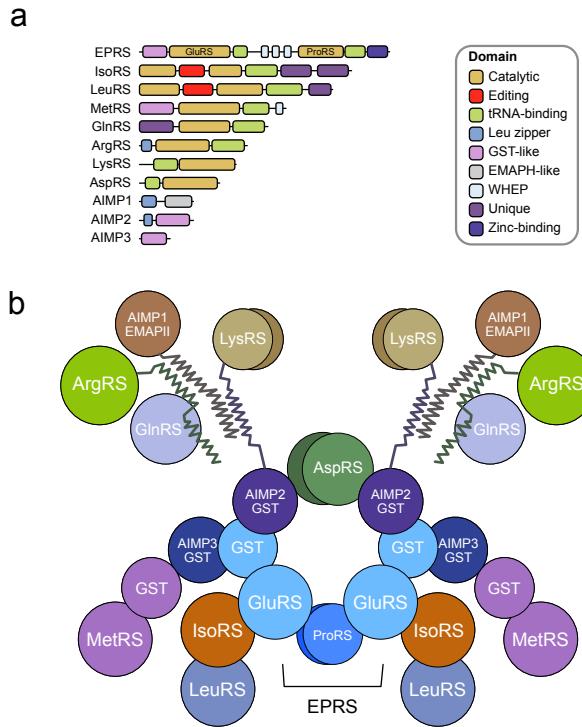

Figure 2.1: The human multi-tRNA synthetase complex (MSC) and its components. **A)** The domains of the aminoacyl-tRNA synthetases and auxiliary proteins (AIMP1, 2 and 3) making up the human MSC. The bifunctional enzyme EPRS1 is made up of the class 1 enzyme GluRS and class II enzyme ProRS (dimer) covalently linked by three WHEP domains. **B)** Cartoon representation of a proposed bisymmetrical model structure of the human MSC. An adaption of a figure created by Myung Hee Kim and Sunghoon Kim[123].

which can control the release of its components. The release of components from the MSC has been linked to numerous non-canonical pathways, including cell signalling, metabolism, inflammation and angiogenesis.

Higher eukaryotes usually have extra-domains at the N- or C- terminus of aaRS enzymes compared with lower eukaryotes and prokaryotes, which may partly contribute to MSC assembly. Most human cytoplasmic aaRS enzymes have at least one new sequence extension or domain, most of which are dispensable for enzymatic activity, suggesting they may contribute to the non-canonical roles of aaRS. Additionally, aaRSs are often found in the nucleus of cells, where protein biosynthesis does not occur. The additional evolutionary complexity in human aaRSs and MSC seems to explain the increased physiological complexity and their

functionality in non-enzymatic processes.

Examples of non-canonical MSC functionality include— LARS1 translocating from the MSC to lysosomes, facilitating mTORC1 activation[128]; KARS1 translocating to the nucleus upon immune activation and activating MITF-dependent gene expression in mast cells[129]. Another example is EPRS1 release from the MSC in myeloid cells upon IFN- γ stimulation[130]. IFN- γ induces a network of kinase events (Cdk5, mTORC1 and S6K1 activation) which causes a two-step phosphorylation of two serines in the linker region of human EPRS, and causes its release from the MSC. EPRS1 combines with other proteins (namely NSAP1, L13a and GAPDH) to form the cytosolic IFN- γ activated inhibitor of translation (GAIT) complex, which represses translation of numerous inflammatory-related transcripts, including VEGFA and ceruloplasmin[131].

In addition to the enzymatic components of the MSC, the auxiliary proteins AIMP1, 2 and 3 are also involved in fundamental biological processes. AIMPs exhibit non-canonical functions aside from their roles as scaffolds in the MSC. AIMPs have been linked to numerous biological processes, including involvement in immune regulation, nervous system functions, viral replication, genome stability, angiogenesis, and cancer. AIMP1 interacts with RARS1 and facilitates incoming tRNA substrates to its catalytic site to enhance its enzymatic activity[132]. In addition to improving amino-acyl synthetase activity, secreted AIMP1 has also been shown to be involved in angiogenesis, inflammation induction, wound closure, and maintaining glucose homeostasis[133]. Transforming growth factor β (TGF β) and the DNA damage response have both been shown to cause phosphorylation of AIMP2 and disassociation from the MSC. Released AIMP2 has been shown to act as a pro-apoptotic mediator and tumourigenesis suppressor via various pathways[134]. AIMP3 largely interacts with MARS1, and under conditions initiating the DNA damage response, MARS1 undergoes a conformational change that releases AIMP3 from the MSC[135]. Released AIMP3 acts as a tumour suppressor, translocating to the nucleus and upregulating expression of the tumour suppressor gene p53.

The functional and structural complexity of the MSC is still being revealed. The canonical and non-canonical functionality of MSC components promises an unexplored rich source of potential therapeutic targets, but also lends itself to associated pathology.

2.3 aaRSs in disease

Structural and functional variations in aaRSSs' enzymatic and non-enzymatic activities have been linked to various human diseases. Changes in gene expression, copy number, mutations and genetic variations of aaRSs have been documented in relation to disease[118].

Charcot Marie Tooth (CMT) is a genetically and clinically-presenting heterogeneous group of hereditary peripheral neuropathies. CMT is characterised by progressive degeneration of distal sensory and motor neuron function[136]. Six aaRSs have been linked to CMT through dominant mono-allelic mutations, including GARS1 and YARS1, which are among numerous genetic-loci to have been linked causally to CMT. Drosophila models of CMT have demonstrated that CMT-causing YARS1 mutations lead to a conformational change in YARS1, leading to aberrant interactions with transcriptional regulators in the cell nucleus and aberrant expression of certain transcription factors[137].

Self-targeting of aaRSs as autoantigens has been implicated in autoimmune diseases. “Anti-synthetase syndrome” (ASS) is a heterogeneous group of autoimmune diseases, including interstitial lung disease (ILD), arthritis, idiopathic inflammatory myopathies, myositis and Reynaud’s phenomenon[138]. Autoimmune antibodies against histidyl-, threonyl-, alanyl-, isoleucyl-, phenylalanyl-, glycyl-, tyrosyl-, asparaginyl-tRNA synthetase have been found in approximately 30% of all autoimmune patients[138]. Dysregulation of aaRS has also been noted in other autoimmune diseases, for example multiple sclerosis and immune thrombocytopenia[139].

aaRSs have been linked to viral and bacterial infection. For example, it has been shown that viral infection leads to the phosphorylation of EPRS and dissociation

from the MSC, ultimately blocking PCBP2-mediated mitochondrial antiviral signalling (MAVS) ubiquitination and inhibiting viral replication[140]. Additionally, HIV-1 infection leads to KARS1 release from the MSC, which is partially transported to the nucleus[141]. Blocking this release reduced the infectivity of progeny virions, implying that HIV-1 utilizes a dynamic MSC for enhanced viral replication[141]. In another study, WARS1 was shown to be increased approximately 27-fold in sepsis patients with a bacterial infection compared with healthy controls[142]. Following a range of infections by various pathogens, host monocytes were shown to rapidly secrete WARS1. The secreted WARS1 increased cell surface levels of CD40, CD80 and CD86, markers of macrophage activation[142].

2.3.1 aaRSs in cancer

A growing number of studies have implicated aaRSs and MSC components in tumourigenesis. Firstly, aaRS enzymatic activity is essential to sustain tumour growth. In cancer metabolism, biosynthesis of aminoacyl-tRNAs has been shown to be highly up-regulated[143]. In cancer, we see often see dramatic rapid cell growth, this demands an intense increase in overall protein synthesis. To keep up with this demand, the canonical aminoacylation role of aaRSs is crucial as the first step in protein synthesis.

On top of the enzymatic role of aaRSs, their non-canonical functionality has also been associated with both promoting and inhibiting cancer. The hallmarks of cancer-enhanced growth signalling and proliferation, vascularization, metastasis, altered metabolism, and immune/tumour microenvironment invasion, all have links to aminoacyl-tRNA synthetase function. Cancer cells require enhanced growth signalling and proliferation to maintain their rapid growth beyond the capacity of normal cells, several aaRSs have been linked to this aberrant growth signalling. GlyRS has been shown to be integral for cancer-promoting neddylation (where ubiquitin-like protein NEDD8 is conjugated to its target proteins) to occur, and reduced MetRS expression resulted in reduced tumourigenicity in p16INK4a-negative breast cancer cells *in vivo*[144–146]. For tumours to grow and metastasize they need

to hijack existing vasculature to get blood flow to growing tumour area, or make new vessels by promoting angiogenesis. Endothelial cells (EC) exposed to TNF- α or VEGF secrete ThrRS. ThrRS promotes EC migration and angiogenesis. Inhibition of ThrRS was shown to inhibit angiogenesis, with and without inducing the uncharged tRNA response[147, 148]. LysRS has been shown to support metastasis by increasing migration. Following phosphorylation by the MAPK pathway, LysRS binds to the 67kDa membrane bound laminin receptor protein (67LR), preventing its degradation and sustaining laminin-dependent migration. Once bound to LysRS, 67LR also binds integrin $\alpha 6\beta 1$, which initiates ERK and paxillin signalling, increasing migration by altering cell-cell and cell-ECM adhesion.

aaRSs have also been linked to altering metabolism in cancer. To make rampant growth feasible, cancer cells adjust metabolism to meet energy demands and provide building blocks for biosynthesis. LeuRS activates the mTORC1 pathway, which controls translation and autophagy. Cancer cells utilize the mTORC1 pathway to proliferate more efficiently. The mTORC1 pathway also causes phosphorylation of EPRS and the release of it from the MSC. In adipocytes, released EPRS interacts with FATP1 and directs it to the plasma membrane. Inhibition of FATP1 leads to increased cell viability in breast cancer cell lines, and its expression correlates with decreased patient survival in triple negative breast cancer[149].

2.3.2 AIMP_s in cancer

As well as the association between aaRSs and cancer, AIMP_s have also been shown to play a role in signalling pathways relevant to numerous cancers. The MSC-bound aaRSs seem to predominantly promote tumourigenic functions when released from the MSC. In contrast, the AIMP_s bound with them seem to have more tumour-suppressive effects. AIMP2 has been shown to be a potent tumour suppressor, working via key regulators in the p53, c-Myc, Wnt, TGF- β and TNF- α signalling pathways. Loss of a single allele of AIMP2 in mice resulted in a far higher susceptibility to tumour formation[150]. AIMP1 has also demonstrated tumour-suppressive effects. In mouse xenograft models, administered AIMP1 was found to

reduce tumour volume[151, 152]. AIMP1 has been shown to induce apoptosis of endothelial cells, such that it suppresses tumour vascularization[153]; it also stimulates anti-tumour immune responses, for example activating NK cells via macrophages, dramatically reducing lung metastasis of melanoma cells[154]. AIMP3 activates the tumour-suppressor gene p53 following DNA damage or oncogenic stress. Loss of an AIMP3 allele results in higher susceptibility to spontaneous tumour formation[155].

2.4 aaRSs as therapeutic targets

aaRSs are considered attractive drug-targets. Initially, the interest in aaRSs as therapeutic targets arose with the detection of differences between prokaryotic and eukaryotic aaRSs. Thus, enabling specific targeting of microbial aaRSs with minimal effect on the homologous human aaRSs, making aaRS inhibitors attractive anti-microbial candidates.

2.4.1 Antibacterials and antifungals

In the 1990s, mupirocin (brand name Bactroban) was approved as an antibiotic for the topical treatment of bacterial skin infections. Mupirocin selectively inhibits bacterial IleRS, by simultaneously occupying isoleucine and AMP binding sites and inhibiting aminoacylation[156]. Mupirocin has shown high selectivity for bacterial IleRS over mammalian IleRS (greater than 8000 fold)[157]. This conferred selectivity seems to be due to only a two-amino acid residue difference in the active site of eukaryotic and prokaryotic IleRS[158]. Another example is Kerydin (Tavaborole or AN2690), an anti-fungal used to treat onychomycosis (a fungal infection of the nail)[159]. Kerydin targets the editing site of fungal LeuRS. Kerydin contains boron (Benzoxaborole)[159]. The boron atom of Kerydin binds to the terminal tRNA^{leu} ribose, trapping tRNA^{leu} in the editing site, causing a non-productive enzyme conformation and inhibiting protein biosynthesis.

2.4.2 Anti-parasitics

On top of the success of the druggability of aaRS enzymes for bacterial and fungal infections, aaRSs have also shown promise as an anti-parasitic target. Much like cancer, some parasites are extremely reliant on protein synthesis to keep up with rapid cell growth and continuous proliferation, so are likely to be more sensitive to disruptions to aminoacylation. Additionally, the evolutionary distance between parasitic aaRSs and human aaRSs is quite large, in fact several parasites have bacterial-like protein translation pathways, not shared by humans[160]. Numerous aaRSs have shown promise as targets for anti-parasitic agents. Several naturally occurring compounds target the AsnRS site of parasites, such as *Brugia malayi*, a nematode which causes Lymphatic Filariasis. *Trypanosoma brucei* has also been shown to be susceptible to aaRS inhibition, for example by Benzoxaboroles targeting LeuRS, or by Aminoquinolines and Benzimidazoles targeting MetRS. The parasite *Plasmodium falciparum* has been shown to be affected by numerous aaRS inhibitors, including mupirocin, cladosporin and febrifugine derivatives.

2.4.3 Febrifugine and its derivatives

Dichroa febrifuga has been used for centuries in Chinese medicine as an antimalarial remedy, it is considered one of the 50 fundamental herbs. In 1948, two quinazoline alkaloids, named febrifugine (FF) and isofebrifugine, were first isolated from the plant *Dichroa febrifuga* (Figure 2.2)[161], as part of a directive to find new antimalarials from plant sources. Although febrifugine has excellent anti-parasitic activity, it also has strong liver and gastrointestinal toxicity, limiting its use as a widespread therapeutic. This motivated the generation of febrifugine derivatives with the hope of reducing off-target toxicity. The medical applications of the long-used traditional anti-parasitic agent febrifugine and its derivatives have recently attracted much attention. Febrifugine derivatives have been used to treat malaria, fibrosis, inflammatory diseases and cancer.

Figure 2.2: Chemical structures of prolyl-tRNA synthetase (ProRS/PARS1) inhibitors. Febrifugine and isofebrifugine were first isolated from *Dichroa febrifuga* in 1948. Halofuginone is a derivative of febrifugine, first synthesized in 1967.

2.5 Halofuginone

One such analogue, a synthetic racemic halogenated derivative of febrifugine, halofuginone (HF; Figure 2.2), was synthesized in 1967 by American Cyanamid Company[108]. Halofuginone was found to have the most potent anti-malarial activity of the FF analogues in vitro and affected all three stages of *Plasmodium falciparum* (ring stages, trophozoites and schizonts) with equal speed, unlike many other chemicals with antimalarial effects. The addition of bromine on the quinazoline ring in HF was found not to affect its antimalarial properties, whilst lowering the cytotoxicity for host cells compared to FF. However, HF does still demonstrate some toxicity to the liver, among other side effects, including diarrhoea and vomiting[109]. In an attempt to reduce the side effects of HF and increase the therapeutic window, trans-enantiomers (2R,3S / +) and (2S,3R / -) of HF have been prepared. Although (-)-HF was found to have lower toxicity than its optical antipode, it was also found to be less efficacious than (+)-HF[162, 163]. This suggests that the biological activity and mammalian toxicity of HF reside with the same enantiomer, therefore there is no advantage to using a specific enantiomer over the racemic mixture.

Recently halofuginone has been researched extensively in association with its applications to non-parasitic diseases. HF is FDA-approved as a feed additive for poultry to prevent coccidiosis from the protozoa *coccidian*. HF has also received orphan drug status for scleroderma and Duchenne muscular dystrophy (in which fibrosis is the main complication). HF has undergone clinical trials as a potential therapeutic in a number of conditions, including cancer[164, 165].

2.5.1 Halofuginone's antifibrotic properties

Fibrosis (or fibrotic scarring) is a pathological feature of most chronic inflammatory diseases, which can be induced by a variety of stimuli[166]. Fibrosis is defined by the accumulation of excess extracellular matrix (ECM) components, especially collagen type I. If highly progressive, fibrosis can eventually lead to organ malfunction and death[166]. ECM turnover is altered in most pathological states associated with fibrosis. TGF β , the tissue inhibitor of metalloproteinases (TIMPs), and matrix metalloproteinases (MMPs) play an essential role in the regulation of the ECM turnover. Inflammatory cells are the main source of TGF β , which induces collagen gene expression and is one of the leading candidates thought to elicit overproduction of ECM proteins in various fibrotic conditions.

Targeting components of the ECM has proved challenging, limiting the success of fibrosis treatment. HF has been found to have antifibrotic properties and the capability to elicit resolution of established, pre-existing fibrosis, not only act preemptively[167]. HF has been shown to reduce collagen synthesis, a hallmark of the disease[168]. HF is thought to regulate downstream effectors of the TGF β signalling pathway by inhibiting Smad3 phosphorylation, which in turn causes a reduction in fibroblast differentiation and levels of ECM proteins[109].

2.5.2 Halofuginone and the amino acid starvation response

Until the last decade, the mechanism of action of halofuginone was unclear, until two papers authored by the same group in 2009[169] and 2012[170] elucidated HF's target and downstream effects. In the 2009 paper, the group demonstrated using mouse

T_{H17} cells that HF activates the amino acid starvation response (AAR) pathway. Mouse T_{H17} cells were treated with HF or an inactive derivative (MAZ1310) for 3 or 6 hours and microarray analyses were performed. ATF4 target genes were found to be activated by HF expression, including Asns, Chop, eIF4Ebp, Gpt2, as well as amino acid transport genes, such as Slc6a9 and Slc7a3, both features that correspond with activation of the AAR. Using western blots, the group also showed that general control nonderepressible-2 kinase (GCN2) autophosphorylation was activated by HF treatment, further indicating HF activates the AAR pathway. This effect was not limited to T_{H17} cells, the AAR pathway was also activated by HF treatment in fibroblasts and epithelial cells[169]. However, this paper did not elaborate on how HF activated the AAR.

In 2012, the group identified HF's target protein and demonstrated that HF and FF activate the AAR by competing with proline as potent inhibitors of tRNA^{pro} charging activity of EPRS. Rabbit reticulocyte lysate (RRL) was used as an in vitro translation system. Following supplementation with excess amino acids, only proline was shown to restore translation inhibited by HF in the RRL system. Moreover, HF-derivatives that were shown to be inactive in functional cell-based assays, such as MAZ1310, also lacked activity in the RRL assay. Together, this suggests that HF functionality is linked to blocking proline utilization. To further demonstrate that HF and FF affect proline utilization, the group synthesized DNAs encoding two epitope-tagged polypeptides, one encoding a proline-dipeptide (ProPep), the second encoding a proline-free peptide (NoProPep). HF and FF treatment prevented translation of ProPep, but had no effect on NoProPep translation[170].

Next, the group investigated the effect of HF on prolyl-tRNA charging and the bifunctional enzyme EPRS (comprised of GluRS and ProRS fused together). The addition of EPRS from purified-rat-liver reduced the sensitivity of RRL to HF. They then investigated the inverse using siRNA-mediated knockdown to reduce EPRS levels in lung fibroblasts. Lung fibroblasts have high levels of EPRS endogenously, so are quite resistant to HF treatment. The reduction of EPRS levels sensitized the cells to HF treatment and AAR pathway activation— GCN2 autophosphorylation

was induced as well as ATF4 response genes, such as CHOP and ASNS. Together this established for the first time that EPRS is a critical target of inhibition for HF and FF, through which the compounds elicit AAR activation. The group demonstrated that HF inhibits EPRS in a competitive fashion with proline at the prolyl-tRNA synthetase active site. HF binding is an ATP-dependent process. ATP directly locks onto and positions HF onto human ProRS so that one part of HF mimics bound proline and the other mimics the 3' end of bound tRNA^{pro}[171]. Excess proline addition was shown to abrogate AAR activation and reversed the biological effects of HF[170].

By binding the active site of ProRS, HF blocks proline from binding and inhibits ProRS enzymatic activity. This results in an intracellular build-up of unaminoacylated (uncharged) tRNA^{pro}s, mimicking the cellular state of proline deficiency, thus triggering the amino acid starvation response. Uncharged tRNAs bind to the protein kinase GCN2 and stimulates its dimerization and autophosphorylation. Activated GCN2 phosphorylates eukaryotic translation initiation factor 2A (eIF2 α), this leads to a reduction in most protein synthesis, whilst increasing translation of ATF4. ATF4 is a transcription factor of the cAMP response element binding protein (CREB) and induces the expression of many genes involved in the integrated stress response (for example DDIT3/CHOP), amino acid synthetases and transporters, aminoacyl-tRNA synthetases, and autophagy regulators (Figure 2.3)[169, 172].

Proline is abundantly incorporated into collagen – together with hydroxyproline, it constitutes more than 25% of residues in collagen, which is the predominant protein (80%) in the ECM[173]. Both hydroxyproline and proline are essential for collagen biosynthesis, structure, and strength[174]. So perhaps the anti-fibrotic properties of halofuginone could also be in part because of the proline-richness of collagen, which inhibition of the canonical function of tRNA^{pro} charging interferes with.

2.5.3 Halofuginone and cancer

HF has exhibited anti-cancer effects in numerous studies and different cancers, including metastatic brain tumours, bladder carcinomas, prostate cancer, renal

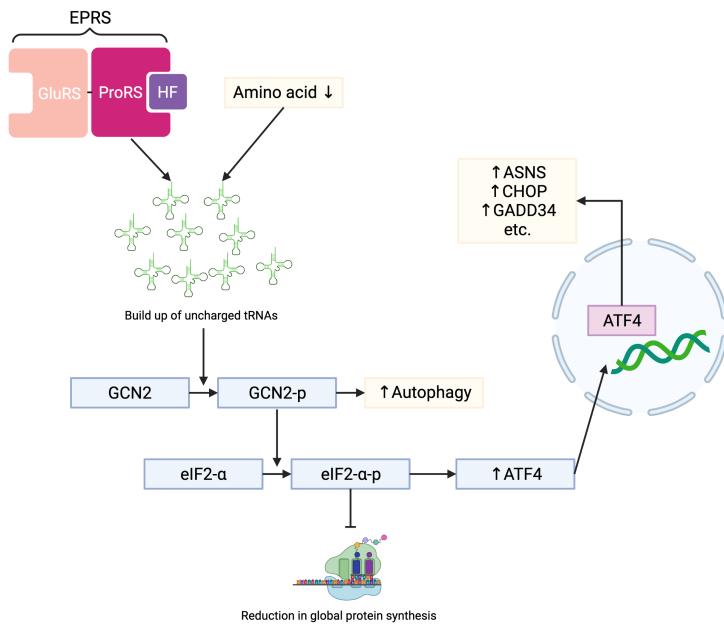

Figure 2.3: Halofuginone (HF) and the amino acid starvation response (AAR). HF binds to the catalytic site of prolyl-tRNA synthetase (ProRS) of the bifunctional aminoacyl-tRNA synthetase, EPRS, and causes an accumulation of uncharged tRNAs, mimicking the same cellular environment as if the cell were amino acid deprived. Uncharged tRNAs bind to the cellular sensor GCN2 and trigger autophosphorylation and activation of GCN2. Activated GCN2 then phosphorylates eIF2- α . eIF2- α -p reduces global protein synthesis, except for mRNAs containing an upstream ORF cluster in their 5' untranslated region (UTR) which are efficiently translated upon eIF2- α phosphorylation[172], including the transcription factor ATF4. Upregulated ATF4 results in increased expression of many genes involved in stress responses (e.g. *DDIT3* [CHOP]), amino acid metabolism, amino acid synthetases (e.g. *ASNS*) and other aminoacyl-tRNA synthetases.

carcinomas, pheochromocytomas, hepatocellular carcinomas, oesophageal squamous carcinomas, lung cancer and breast cancer[110–114, 175–178]. HF has been shown to exert anti-cancer effects in numerous manners, including reducing tumour growth, reducing angiogenesis, activating autophagy and apoptosis, and disrupting the collagen network of tumours, among other mechanisms.

Halofuginone and MM

As mentioned in Section 1.3, MM is an incurable cancer of plasma cells. Drug resistance is a severe problem in MM, with patients becoming resistant to previous drug treatments. Therefore, identifying novel therapeutics for the treatment of MM is of critical importance.

Following the success of HF treatment in numerous preclinical cancer studies and the phase II study of HIV-related Kaposi's sarcoma[179], Leiba et al. (2012) investigated the treatment of HF in multiple myeloma, both *in vitro* and *in vivo*[115]. 17 MM cell lines were treated for 48 hours with a range of HF concentrations. HF was shown to induce a reduction in cell viability in a dose-dependent manner across all 17 MM cell lines, with an IC₅₀ of approximately 100nM in most cell lines. The effect of HF on primary cells was then investigated. BM CD138⁺ cells from five MM patients and PBMCs from two healthy donors were treated with a range of HF concentrations. A greater dose-dependent reduction in cell viability was seen in the primary MM cells compared to the healthy PBMCs, with an IC₅₀ ranging from 101-253nM for the MM cells. Demonstrating that HF specifically inhibits the viability of MM cells while having no significant effect on normal cells (at the given concentration range), this also gave a therapeutic window for HF in MM. Next, the group demonstrated that HF induces apoptosis in MM—HF treatment triggered caspase 3, 8 and 9 activities in MM cell lines in a dose dependent manner; it increased the quantity of apoptotic cells (Annexin V-FITC apoptosis assay); it caused an accumulation of cells in sub G1 phase of the cell cycle, associated with DNA fragmentation; and it elevated expression of the heat shock protein Hsp-90. They also showed that exogenous IL-6 and IGF-1, which are central for MM growth and survival, did not rescue HF-induced cytotoxic effects on MM cell lines, indicating that paracrine MM cell growth and the BM environment are unlikely to reverse the biological effects of HF.

The group also exhibited the anti-MM effects of HF *in vivo*, using in a xenograft model of SCID mice injected with MM.1S cells. Once tumours reached sufficient size, mice were treated with either PBS or HF for five days a week for the duration of the experiment. HF treatment was found to inhibit tumour growth and increase overall survival compared to the control mice.

Synergy of HF with existing MM drugs was investigated[115]. Cells were cultured for 48 hours with HF (25, 50 and 100nM) in combination with 5nM Bortezomib, 25uM lenalidomide, 500nM dexamethasone, or 500nM doxorubicin. Cells were

cultured for 24 and 72 hours with HF (25, 50 and 100nM) in combination with 10uM melphalan. CalcuSyn software (Biosoft, Ferguson, MO, USA) was used to evaluate synergism. Lenalidomide, dexamethasone and doxorubicin were found to be synergistic or additive with HF in all MM cell lines. HF showed moderate antagonism in combination with Bortezomib. However, only one concentration value was used for each of the established MM agents, and a small range of concentrations were used for HF treatment. A larger range of concentrations of both HF and the other agents would be required to gain a greater insight into the drugs interactions with one another.

From this study, it is clear HF is effective against MM, and could show promise as a potential line of therapy. However, Leiba et al. (2012) did not show how HF was exerting its effect, or if the AAR was activated. AAR activation results in upregulated levels of the transcription factor ATF4. It would be interesting to explore the transcriptional landscape of MM cells and the tumour microenvironment following HF treatment, to see how AAR activation affects this. The group used MM cell lines, mouse models and primary BM samples from MM patients. The primary BM samples were compared against healthy donors' PBMCs and not MM patients' own non-myeloma cells, so only limited conclusions can be drawn about HF's specificity for MM cells over normal cells. Moreover, MM cells are known to interact substantially with their microenvironment. In this study, the cells were studied in isolation, the effect of HF on the immune microenvironment was not investigated. The paper states that BM samples were taken from five MM patients, however it is not stated what stage of disease progression the patients were in, or if they were a mixed group of patients in various disease stages. Therefore, conclusions cannot be drawn whether HF is equally or preferentially effective against newly-diagnosed and relapsed MM patients.

2.6 Discussion

Considering aaRSs are such a highly conserved and ancient family of enzymes, it is surprising how much about their structure and function is still unknown. Concerted

efforts are being made to elucidate the full structure of the MSC, with this knowledge, the full functionality of the MSC might be more clearly understood too. More non-canonical functions of aaRSs are being revealed, and with it, associated pathologies. This also presents unexplored potential for aaRS therapeutics.

Drugs targeting aaRSs have shown effectiveness in a wide range of clinical settings including numerous cancers. aaRS inhibitors are an exciting drug class in the application of cancer, as tumours often have such a high protein biosynthesis burden, especially MM with the overproduction of large quantities of paraprotein. Therefore, targeting the first step in protein biosynthesis is highly attractive. Halofuginone, an inhibitor of the ProRS active site of EPRS, has been researched extensively in recent years. HF has shown anti-MM effects against MM cell lines, *in vivo* mouse models and primary patient BM samples.

HF has been shown to activate the amino acid response in rabbit reticulocyte lysate and lung fibroblasts. HF's effects are abrogated by excess proline supplementation. HF also demonstrates substantial liver and GI toxicity, so may not be able to be used as a widespread drug in cases without orphan drug status. A ProRS inhibitor which was less toxic, with a wider therapeutic range and whose effects could not be overcome by excess proline would likely be a much more effective anti-cancer agent therapeutically.

The mechanism of action of HF in MM has not been clarified and the transcriptional changes of HF treatment in MM have not yet been described. MM patient cells have only been studied in isolation—MM patients' immune microenvironment following HF treatment has not been investigated. The specificity of HF for MM cells has also not been demonstrated fully. MM patients' transcriptome, epigenome and genome evolves greatly during disease progression, and the changes are not limited to MM cells and plasma cells. Therefore, the effect of HF treatment on MM cells must be compared to the patient's own non-myeloma cells to be able to assess specificity, rather than healthy donor's PBMCs, as they are so different from the PBMCs of MM patients. It would be hugely pertinent to employ single-cell sequencing of BM samples following HF treatment. scRNA-seq could capture transcriptional changes

of the MM cells and their surrounding immune microenvironment, and would also allow composition analysis, so that proportional changes of each cell type could be quantified, and HF's specificity for MM cells evaluated.

So far, only BM samples from MM patients of unknown disease progression have been treated with HF. Therefore, no comment can be made on whether HF works on relapsed patients' MM cells. Various MM cell lines have been treated with HF, however the resistant variants were resistant to traditional chemotherapy agents (Doxorubicin, Mitoxantrone and Melphalan) or Dexamethasone. MM is conventionally treated with a three-drug regimen (as discussed in Section 1.3.6), comprising a corticosteroid (e.g. Dexamethasone), a proteasome inhibitor (PI; e.g. Bortezomib or Carfilzomib), and an immunomodulatory drug (IMiD; e.g. Lenalidomide). MM patients eventually accrue resistance to all three drugs in the regimen. HF's anti-MM effects were not demonstrated against either PI-resistant or IMiD-resistant cell lines or relapsed patients. It would be interesting to see if HF's anti-MM effects are maintained in PI-resistant MM cells. Proteasome inhibition leads to an accumulation of misfolded, damaged or unneeded proteins, which activates the unfolded protein response (UPR), which in part contributes to the anti-MM effects of PIs. The UPR and AAR share many joint effectors, such as *ATF4* and *DDIT3*, both contributing to ER stress and apoptotic mechanisms. As there is some overlap with HF's and PIs' mechanisms of action, and that Leiba et al. (2012) reported mild antagonism of HF in combination with the PI bortezomib[115], you may not expect HF to be effective against PI-resistant MM. Many new MM agents are approved for relapsed MM initially, rather than as first-line treatments; therefore, it would be critical for ProRS inhibitors' success in myeloma that their anti-MM effects extend to PI-resistant and relapsed MM. This is crucial question that must be answered.

Another point that would be of interest to investigate, is the interaction of HF treatment and EPRS's non-canonical functionality. Following IFN- γ stimulation, the EPRS dissociates from the human MSC to participate in the GAIT complex in myeloid cells. The GAIT complex represses translation of inflammatory-related genes, including *VEGFA*. It would be interesting to see if HF has any effect on

this non-canonical function of EPRS, or in fact, if the GAIT complex impacts HF treatment in myeloid cells.

aaRSs are a very exciting area of research, particularly as drug targets. So far, the application of aaRS inhibitors in disease has only scratched the surface of their potential as therapeutics. Much more work is required to fully understand their mechanism of action and breadth of potential applications in disease, particularly MM.

3

Methods

3.1 Cell culture

3.1.1 AMO-1 cells

AMO-1 cells, plasma cells derived from a 64-year old female myeloma patient, were used as a model cell-line for multiple myeloma. PI-sensitive cells are referred to as WT cells in this work. Bortezomib resistant (aBTZ) and carfilzomib resistant cells (aCFZ) (believed to be AMO-1 cells) were generated and gifted by the Driessen lab[180]. After typing these cells, they were found to be a mix of AMO-1 cells and L363 cells. AMO-1 cells were cultivated in RPMI-1640 medium (Thermofisher, UK), supplemented with 10% fetal bovine serum (FBS) and 2mM L-glutamine (Invitrogen, UK). Cells were passaged when they reached approximately 1.5-2 million cells per ml. AMO-1 cells are suspension cells and were split twice a week to approximately 0.5 million cells per ml. All media was replaced with fresh media every two to three weeks, or prior to performing experiments with the cells.

3.1.2 L363 cells

After typing the cells gifted by the Driessen lab, they were found to be a mix of AMO-1 MM cells and L363 MM cells. In-house PI-resistant cell lines were produced by Dr James Dunford by continued and escalating drug exposure of drug-sensitive (WT) AMO-1 cells. However after these cells were typed, they were found to be L363 cells. This was due to the drug exposure selecting the L363 contaminant population

over the AMO-1 cells, due to their innate increased resistance to PI, compared to AMO-1 cells. Once this mistake made by our collaborators was noticed, WT L363 cells were purchased. WT, aCFZ and aBTZ cells were cultivated in RPMI-1640 medium (Thermofisher, UK), supplemented with 10% fetal bovine serum (FBS) and 2mM L-glutamine (Invitrogen, UK), and kept in 100nM of their respective proteasome inhibitor. Cells were passaged when they reached approximately 1.5-2 million cells per ml. L363 cells are suspension cells and were split twice a week to approximately 0.5 million cells per ml. All media was replaced with fresh media every two to three weeks, or prior to performing experiments with the cells.

L363 cells resistant to NCP26 (NCP26R) were also developed by Dr James Dunford by continued and escalating drug exposure of WT L363 cells to NCP26.

3.2 Compounds

3.2.1 Proteasome inhibitors

Stock concentrations of PIs, bortezomib (BTZ) and carfilzomib (CFZ) were purchased from Thermofisher, UK. BTZ and CFZ were made up to desired concentrations with DMSO.

3.2.2 ProRS inhibitors

The synthesis of NCP22 (T-3767758) is detailed in [181]. NCP26 was synthesised by collaborator, Dr Ralph Mazitschek, co-discoverer of HFG mechanism, as a novel inhibitor of ProRS enzymes, synthesis detailed in [182] (currently under review). ProRS inhibitors: halofuginone (MAZ1392; HF) and halofuginol (MAZ1805), NCP26 and NCP22 were provided by Dr Mazitschek. The chemical structures of these compounds are shown in Figure 3.1.

Figure 3.1: ProRS inhibitor chemical structures.

3.3 Assays

3.3.1 Cell viability assays

10X presto blue was added directly to the cell media in a 1:10 ratio and incubated at 37°C for two to three hours. The fluorescence was measured at 560 nm excitation and 590 nm emission on FLUOstar OMEGA (BMG Labtech, Offenburg, Germany).

3.3.2 Dose-response curves

90µl of cells in fresh media were seeded in single wells into 96-well plates a day prior to treatment with compound. A total of 20,000 cells were seeded into each well.

No cells were placed in edge wells, to avoid edge effects. The following day, media 0% viability controls were placed in the first and last row. Drug concentrations were made up 1000x the desired final concentration. Drugs were diluted once in media (usually 1 in 100), then into the final plate with seeded cells (usually in 10), depending on the experiment. All drug concentrations/combinations were performed in triplicate. Cells were treated with 0.1% DMSO final concentration in triplicate as 100% viability controls. DMSO concentration was kept the same ($\leq 0.1\%$) for every sample across an experiment, to minimise its toxic effects and to keep its effects consistent across conditions.

3.4 Bulk RNA-seq

3.4.1 RNA extraction

RNA was isolated and purified using the Direct-Zol RNA MiniPrep kit (Zymo, USA), following the manufacturer's protocol. In brief, for each sample, approximately 100,000 cells were lysed in 300 μ l of TRIzol and the lysate was transferred to a microcentrifuge tube. 300 μ l of ethanol was added to the lysed samples and vortexed. The mixture was transferred to miniPrep columns and centrifuged at 13,000g for 30 seconds. The column was washed twice with 400 μ l of Direct-Zol pre-wash and once with 700 μ l of RNA wash buffer. The column was transferred to an RNase-free tube and eluted with 50 μ l of nuclease-free water and centrifuged.

The RNA concentration was quantified using a NanoDrop ND-1000 Spectrophotometer (Thermo Fisher Scientific, USA), and samples were stored at -80°C.

3.4.2 RNA library preparation

Samples were normalised to 100ng and made up to 50 μ l with nuclease-free water. NEBNext Ultra II directional RNA library prep kit for Illumina with TruSeq indexes was used to prepare RNA libraries, following the manufacturer's protocol. Samples were plated onto Eppendorf DNA lobind 96 well plates. A VIAFLO robot was used to reduce time spent on washes and precipitations. Volumes were adjusted for elution steps to account for the dead volume of the robot. Prior to any steps involving the

VIAFLO robot, thermocycler, or incubations on the magnetic rack, plates were sealed tightly with foil lids, briefly vortexed and then centrifuged for < 10 seconds at 100g. Polyadenylated RNA was enriched using the NEBNext Poly(A) mRNA magnetic isolation module (NEB, USA), following the manufacturer's instructions with several modifications. Oligo dT Beads were washed appropriately, then 10 μ l of oligo dT Beads (manufacturer's protocol says 20 μ l) was added to each RNA sample, and incubated for 10 minutes at room temperature. Following polyA selection and first and second strand synthesis, cDNA was purified using 1.8X solid-phase reversible immobilisation (SPRI) beads. Purified cDNA was eluted in 55 μ l 0.1X TE Buffer. The cDNA was then end-prepared and adaptor ligated. The cDNA was diluted 50-fold in the adaptor dilution buffer (as 100ng starting RNA was used). PCR amplification was carried out using 11 PCR cycles (the manufacturer's protocol recommends 12-13 for 100ng starting RNA), in order to minimise PCR duplicates.

3.4.3 Pre-sequencing preparation

The molarities of the libraries were determined by electrophoresis on an Agilent 22000 TapeStation (Agilent, USA) and High Sensitivity D1000 ScreenTape (Agilent, USA). The samples were then pooled according to their peak molarity. The pooled library was again quantified using an Agilent 22000 TapeStation (Agilent, USA) and High Sensitivity D1000 ScreenTape (Agilent, USA). If significant adaptor-dimers were present, then an extra clean-up using 1.2X SPRI beads was performed. The pooled library was then denatured and diluted ready for sequencing. In short, 10 μ l of the approximately 2nM library was denatured with 0.2N 10 μ l NaOH. The mixture was vortexed briefly, centrifuged at 300g for 1 minute, and then incubated at room temperature for 5 minutes. 10 μ l 200mM Tris-HCl (pH 7.0) was then added, vortexed and spun as above. The denatured library was then diluted to 20pM. 970 μ l chilled HT1 buffer was added, vortexed and spun. 117 μ l of the 20pM library was then mixed with 1183 μ l chilled HT1 buffer to give a 1.8pM library ready for sequencing on the Illumina NextSeq platform.

Sequencing of the resultant libraries was performed on the NextSeq 500 (Illumina, USA) platform using a paired-end run, according to the manufacturer's instructions.

3.5 Single-cell RNA-seq

3.5.1 Drop-Seq

Cell encapsulation

The Drop-Seq protocol[103] was followed for single-cell RNA-seq sample preparation. Cells were loaded into a microfluidics cartridge. Cell capture, cell lysis and reverse transcription was performed on a Nadia instrument, an automated microfluidics device (Dolomite Bio, UK) Reverse transcription reactions were performed using ChemGene beads.

Library preparation

Beads were collected from the device and cDNA amplification was performed. The beads were treated with Exo-I nuclease prior to PCR. The amplified, purified cDNA then underwent fragmentation reactions. A TapeStation (Agilent, USA) was used to assess library quality. The samples were pooled together and split across multiple sequencing runs. Sequencing of the resultant libraries was performed on the NextSeq 500 (Illumina, USA) platform using a paired-end run, according to the manufacturer's instructions.

3.5.2 10X Chromium V3

Bone marrow samples were collected from two newly diagnosed multiple myeloma patients and two relapsed multiple myeloma patients; anonymised human tissue samples used in this project were obtained with informed consent by the Haem-Bio Tissue Bank (REC reference: 17/SC/0572). After Ficoll gradient separation, mononuclear bone marrow cells were diluted to 500,000 cells/ml in RPMI media supplemented with 2mM L-glutamine and 10% FBS and 1ml was added to 15ml polypropylene tubes. Compounds were dissolved in DMSO, and 1 μ l of compound solution was added to achieve a final concentration of 1 μ M and incubated for 24

hours. Cells were counted and single-cell RNA-seq library preparation was performed using the Chromium Next GEM Single Cell 3' GEM, Library and Gel Bead Kit v3.1 according to the manufacturer's instructions. Indexed libraries were quantitated by TapeStation, pooled and sequenced on an Illumina NovaSeq 6000 (Novogene, UK) platform using a paired-end run.

3.6 Data Processing

3.6.1 Bulk RNA-seq

Fasta files were processed using CGAT-flow[183], the workflow can be found at: https://github.com/cgat-developers/cgat-flow/blob/master/cgatpipelines/tools/pipeline_rnaseqdiffexpression.py. The pseudo-alignment tool, Kallisto[184], was implemented to pseudo-align reads to the reference human genome sequence (GRCH38 (hg38) assembly) and to construct a counts matrix of samples against transcripts. DESeq2[185] was used for differential expression analysis of counts matrices (using negative binomial generalized linear models) within the R statistical framework (v3.5.1). XGR[186], ClusterProfiler[187, 188], Reactome[189], GSEA[190], Gene Ontology (GO)[191] and KEGG[192] were used to perform pathway analysis, within R. Org.Hs.eg.db[193], AnnotationDbi[194] and biomaRt[195] were used for converting between Ensembl IDs, HGNC symbols and ENTREZ IDs.

3.6.2 Single-cell RNA-seq

The computational pipeline outlined in Section 4.2 was used to process scRNA-seq data. Downstream analysis was performed in Jupyter lab notebooks[196] with R kernels. inferCNV[197, 198] was used to detect large-scale chromosomal copy number variations (CNVs) in scRNA-seq data and help inform cell type annotation of the clusters.

4

Computational method development

4.1 Introduction

4.1.1 Reproducible workflows

In data analysis, particularly in bioinformatics, many users create simple bash or R scripts to execute the specific task at hand. However, if this is done frequently, the user will have an accumulation of these single-use scripts, which are often named uninformatively and never used again. This may mean the user creates numerous scripts which perform the same function. Another example of a bad practice is using the command line alone to perform tasks. This means that exactly how the analysis was performed is not recorded and may be lost or difficult to find later. These are bad practices in terms of efficiency and reproducibility. It is much better practice to create well-documented, generalised workflows which can then be applied to multiple different experiments. This enables the user to reuse their code more easily and reproduce results, if need be. This also allows other researchers to reproduce results or apply the code to their own research.

In addition to creating generalised, reproducible workflows, it can be beneficial to create more extensive computational pipelines for jobs which require multiple tasks or actions to be performed sequentially.

4.1.2 Computational pipelines

A computational pipeline consists of a series of manipulations and transformations, where the output of one element is the input of the next. Often these elements are executed in parallel. Pipelining ‘omics’ data-processing means that tasks that are not interdependent can be executed simultaneously. Additionally, multiple samples can be processed in parallel, thereby reducing run time. There are many available pipelining frameworks, for example Snakemake[199], Luigi and Ruffus[200].

For this work, a series of computational pipelines and workflows were generated. Ruffus and CGAT-core[201] were used as the backbone for the pipelines developed.

4.2 scRNA-seq pseudoalignment pipeline

Fewer pipelines exist for single-cell RNA-seq analysis than for bulk RNA-seq. For the Chromium 10X Genomics platform, most of the processing and analysis is automated by Cell Ranger; however for other technologies, the workflow is not as well defined. A single-cell analysis pipeline was constructed with the aim to produce an easy-to-use, robust and reproducible workflow that works for Drop-Seq as well as 10X technology, which utilises pseudoalignment rather than traditional mapping methods.

4.2.1 Psuedoalignment

Traditional mapping techniques such as Tophat[202] or STAR[203], rely on aligning each read to a reference genome. This is generally very time consuming and computationally expensive. Another challenge that arises with traditional mapping is the occurrence of multi-mapping, whereby a read cannot be uniquely aligned as it could map equally well to multiple sites in the genome[204]. More recently, a series of methods called pseudoaligners have been developed that overcome some of the issues associated with traditional mapping approaches. Pseudoalignment (sometimes referred to as quasi-mapping) methods provide a lightweight, alignment-free alternative to traditional mapping. It has been shown that information on where exactly inside transcripts sequencing reads may have originated is not required for

accurate quantification of transcript abundances[205]. Rather, only which transcript the read could have originated from is needed and transcript abundances are calculated by computing the compatibility of reads with different transcripts. This negates the need for alignment to a reference genome, alleviating the issue of multi-mapping and reducing the computational load. Pseudoaligners have been shown to complete data processing of RNA-seq datasets up to 250-times faster than traditional alignment and quantification approaches[184]. Kallisto[184] and Salmon[206] are tools which implement pseudoalignment. They have similar speed and accuracy for bulk RNA-seq data¹.

Pseudoalignment of scRNA-seq

Pseudoalignment tools have recently been developed for droplet-based scRNA-seq analysis (dscRNA-seq). Additional challenges come with dscRNA-seq data processing, having the extra complication of cellular barcodes (CBs) and unique molecular identifiers (UMIs). These tools must handle transcript abundance estimation, as with bulk RNA-seq analysis, but also perform CB detection, collapsing of UMIs (arising from PCR duplication of molecules) and barcode error correction. Kallisto BUS[207] has been developed as an analysis tool and file format specifically for single-cell analysis, alongside BUStools, for processing of the resultant BUS file[208]. Salmon Alevin[209] has also been developed for single-cell RNA-seq analysis.

Pipeline outline

Kallisto BUS and/or Salmon Alevin perform pseudoalignment and generation of a cell-by-gene expression counts matrix. Quality control is performed using Scater[210] and alevinQC. Clustering is performed using Seurat3[211] and Monocle[212]. Clusters are projected onto tSNE and UMAP plots. Differentially expressed genes are identified by performing non-parametric Wilcoxon tests on $\log_2 TPM$ expression values and Fisher's exact test for comparing expressing cell frequency, these p values combined using Fisher's method. Multiple comparisons are accounted for by performing the Benjamini-Hochberg correction to adjust the false discovery rate (FDR).

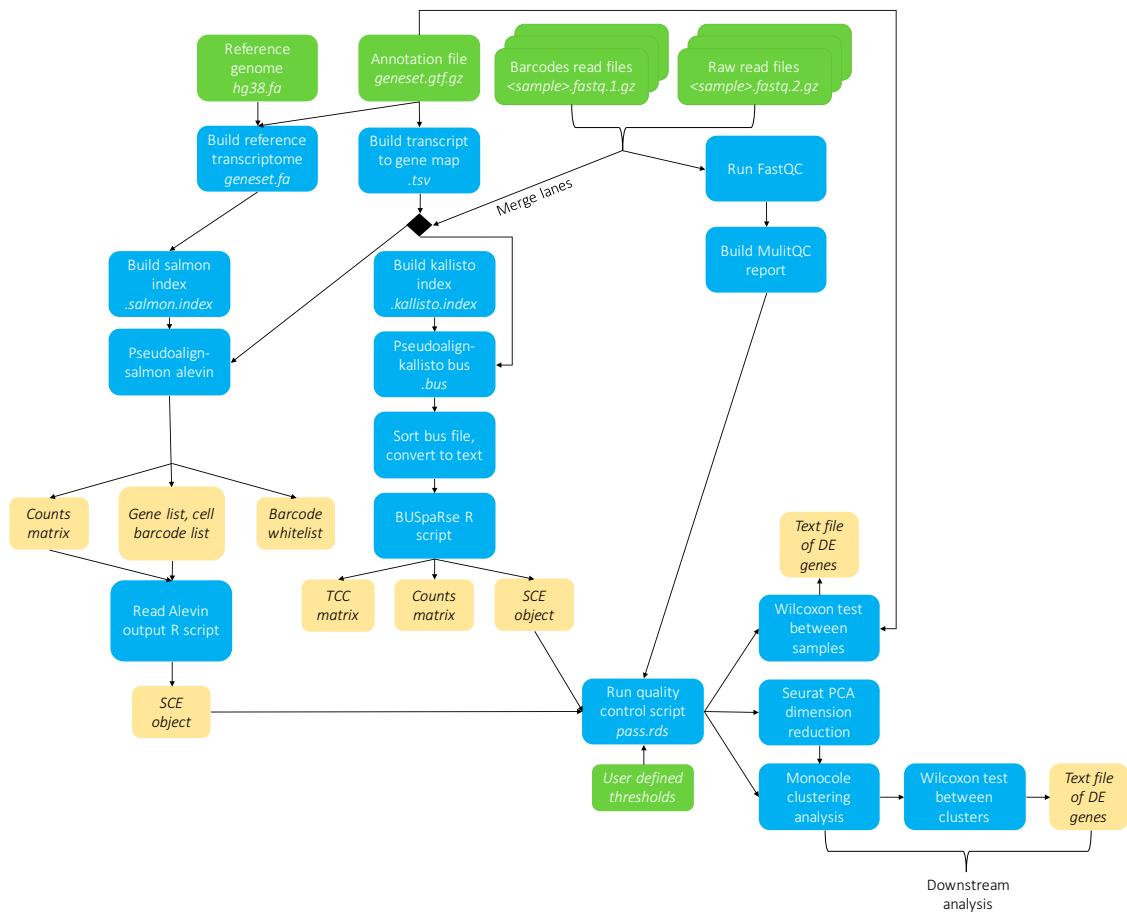

Figure 4.1: Flowchart outlining scRNA-seq pseudoalignment pipeline.

4.2.2 Benchmark

Benchmarking measures the performance of a method/software relative to other methods available. Run time and the accuracy of results are often the factors considered in a benchmark. To be able to calculate the accuracy of results, the ‘true’ results must be known. This is difficult in scRNA-seq analysis as no gold standard analysis protocol exists. Instead, methods are compared against simulated results which act as the underlying ‘ground truth’.

A benchmark was conducted using simulated data, utilising the pseudoalignment pipeline outlined above. Kallisto BUS/BUStools and Salmon Alevin pseudoalignment methods were both implemented and their performance compared to one another. Both pseudoalignment tools have previously been compared to traditional mapping tools[207, 209] and both showed comparable accuracy levels, therefore this

benchmark does not include the performance of traditional mapping methods.

Simulated data

Simulated reads with a known ground truth counts matrix were generated as follows: 10X (version 2) fastq files of 4k PBMCs from a healthy human donor were downloaded². These sequencing files were processed using Salmon Alevin. The resulting Alevin output folder was used as input for Minnow, using Minnow's alevin-mode. Minnow generates droplet-based scRNA-seq simulated reads, working backwards from a known counts matrix to generating raw sequencing files from which the counts matrix could have originated. The valid cell barcode list (whitelist) for 10X chemistry was used (*737K-august-2016.txt*³). Minnow was ran with an error rate of 0.001 and with 12 simulated PCR cycles. Minnow accounts for core experimental dscRNA-seq characteristics, such as PCR amplification bias, barcode sequencing errors, the presence of doublets and ambiguously mapped reads, to try and emulate a realistic set of sequencing reads consistent with the provided counts matrix.

The ground-truth counts matrix was converted to a Single Cell Experiment object (SCE) and the simulated reads were used as input for the scRNA-seq pseudoalignment pipeline. The resulting count matrices outputted by Salmon Alevin and Kallisto BUS were converted into SCEs, subset and reordered so that they all contained the same cells and genes, in the same order. The Salmon Alevin and Kallisto BUS produced SCEs could then be compared to the ground truth SCE.

Run time

The simulated reads consisted of 434 million reads. Running Salmon Alevin and creating an SCE object took approximately 64 minutes; running Kallisto BUS, sorting and creating an SCE object took approximately 24 minutes. Using the bustools 'count' command to create a counts matrix may have further reduced run time, however more time would be needed to parse it into R and create an SCE object.

³<https://github.com/COMBINE-lab/minnow/blob/master/data/737K-august-2016.txt>

Cell barcode handling

The ground-truth data contained 4340 cells. Alevin determined a threshold for the initial whitelist (a set of CBs that likely represent non-empty droplets) by finding a ‘knee’ in the knee plot shown in Figure 4.2. A knee plot is standard for scRNA-seq quality control. Cells are ordered by the number of distinct UMIs observed and a threshold is determined for considering which cells are valid for analysis. For Salmon Alevin this initial whitelist based on the ‘knee’ contained 5261 cell barcodes, each observed at least 191 times. Following barcode error correction, the final whitelist contained 4340 cells, all of which corresponded to the same CBs as the ground-truth data.

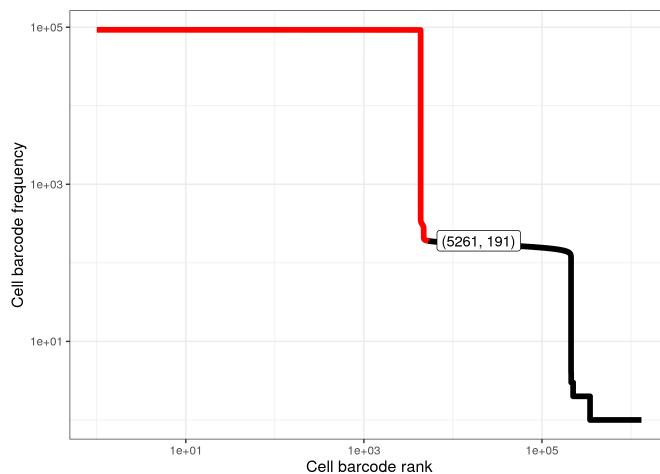

Figure 4.2: Salmon Alevin knee plot. This plot displays the number of times each cell barcode is observed, in decreasing order. Finding a ‘knee’ in this plot determines a threshold for the initial whitelist of CBs, which are unlikely to be empty droplets.

For Kallisto BUS, valid cell barcodes were determined using either `emptyDrops` (`DropletUtils`) or by using `barcodeRanks` and calculating the inflection point of a rotated knee plot (where the x- and y- axis are transposed; Figure 4.3). The inflection point method, gave a whitelist of 4339 cell barcodes (one fewer than the ground truth number), but all 4339 CBs corresponded to ground truth CBs. `emptyDrops` gave a total cell number of 12037, only 3746 of which were in the ground truth list of 4340 CBs. This was a large overestimate of number of cells present and the whitelist

did not contain all of the valid CBs. Therefore, using the inflection point of the rotated knee plot was found to be the preferred method of filtering cell barcodes.

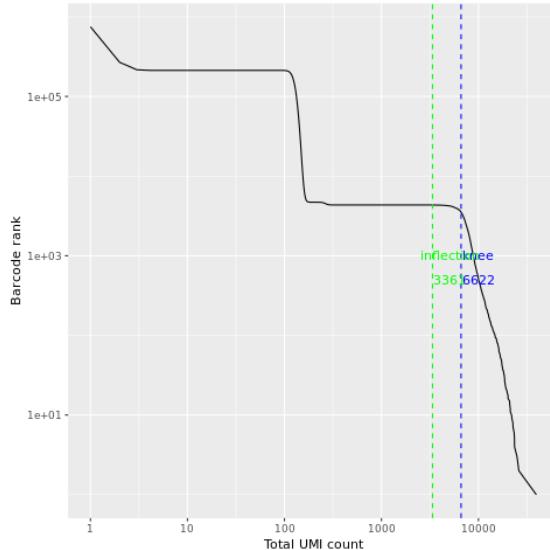

Figure 4.3: Kallisto BUS rotated knee plot. This plot shows the number of distinct UMIs against the rank of the barcode. The Pachter lab transpose the x- and y-axis on their knee plot, so that the x-axis displays distinct UMIs and the y-axis displays ranked cell barcodes, according to the number of corresponding UMIs to each CB. The group state that this is more intuitive for users, as the total UMI count determines the cell barcode rank, and therefore it is more logical to have UMI count as the independent variable on the x-axis.

Gene expression predictive accuracy

To quantify each tool's accuracy of gene expression, precision, recall and F1 scores were calculated for each gene. F1 score is a measure of a test's accuracy, it is the harmonic mean of precision and recall:

$$\begin{aligned} \text{precision} &= \frac{tp}{tp + fp} \\ \text{recall} &= \frac{tp}{tp + fn} \\ F_1 &= 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} \end{aligned} \tag{4.1}$$

Where for each gene: tp = number of true positives, fp = number of false positives, fn = number of false negatives.

		Ground truth	
		Expressed	Not Expressed
Alevin /BUS	Expressed	True positive	False positive
	Not Expressed	False negative	True negative

Table 4.1: Confusion matrix of true/false positives/negatives based on expression between predicted values by Alevin/BUS and the ground-truth matrix.

No expression was denoted by 0, and expression by 1. When recall or precision was undefined, i.e. a gene in Alevin/BUS matrix or the ground-truth matrix was not expressed by any cell, F1 score was defined as 0.

The mean F1 scores for Salmon Alevin and Kallisto BUS processed data (Figure 4.4) were 0.93 and 0.95, respectively. These F1 scores are extremely similar to each other, this is due to a large number of F1 scores equalling 1. Figure 4.5 shows the distribution of F1 scores more clearly. For this dataset Salmon Alevin seemed to produce more lower F1 scores than Kallisto BUS.

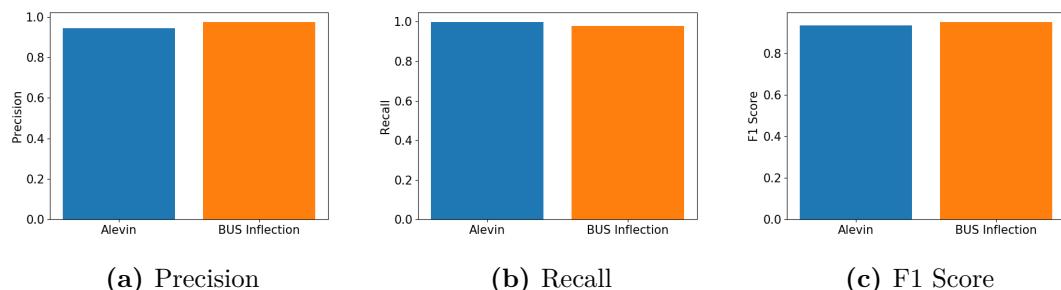

Figure 4.4: Kallisto BUS and Salmon Alevin gene expression performance metrics. Measure of accuracy for the tools ability to predict gene expression. Gene expression classified by 0 or 1. Precision, recall and F1 scores were calculated for each gene across each cell and mean scores were calculated for both pseudoaligner tools.

Clustering

Clustering analysis was performed to visualise how well the tools processed the scRNA-seq data and how clusters compared to ground-truth data. Seurat 3 integrative analysis was performed so that the clusters of each sample could be directly compared. Figure 4.6 shows clustering of Alevin, BUS and ground-truth

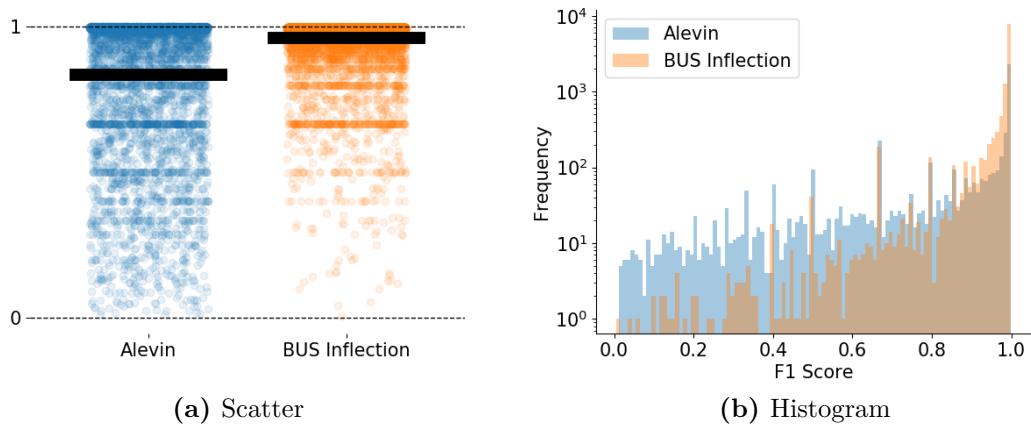

Figure 4.5: F1 score distributions. F1 scores of 0 have been removed. a) F1 score scatter for each gene expressed across all 4339 cells. The black bar denotes the mean F1 score. F1 scores of 0 have been removed. b) Histogram of F1 scores.

clustered data, using UMAP and tSNE dimension reductions. 18 clusters are present in all three of the data sets. Visual analysis suggests that the two dscRNA-seq quantification tools compare well to the ground-truth and capture most aspects of the data. From the benchmark it seems as if both tools are fit for purpose and can accurately quantify gene expression and correctly handle CBs and UMIs.

4.2.3 Updated scRNA-seq pipeline

Following the benchmark it was decided that Kallisto BUS and BUStools would be used to analyse scRNA-seq data. This was due to its faster run-time and higher F1 scores. The analysis pipeline has been updated continually throughout the project. The updated workflow is outlined in Figure 4.7. Each major task has been split into separate lightweight pipelines, each containing multiple minor tasks. The black arrows in Figure 4.7 denote a separate processing pipeline. This allows the user to analyse the output after each step, and make changes to parameters as they see fit.

Following sequencing, raw FASTQ files are used as input for Kallisto BUS. BUS files are generated along with the corresponding information about equivalence classes and transcript names. Kallisto BUStools is used to generate a cell by gene count matrix for each sample. These matrices are loaded into R and converted to Single cell experiment (SCE) and Seurat objects. Next, quality control (QC) is

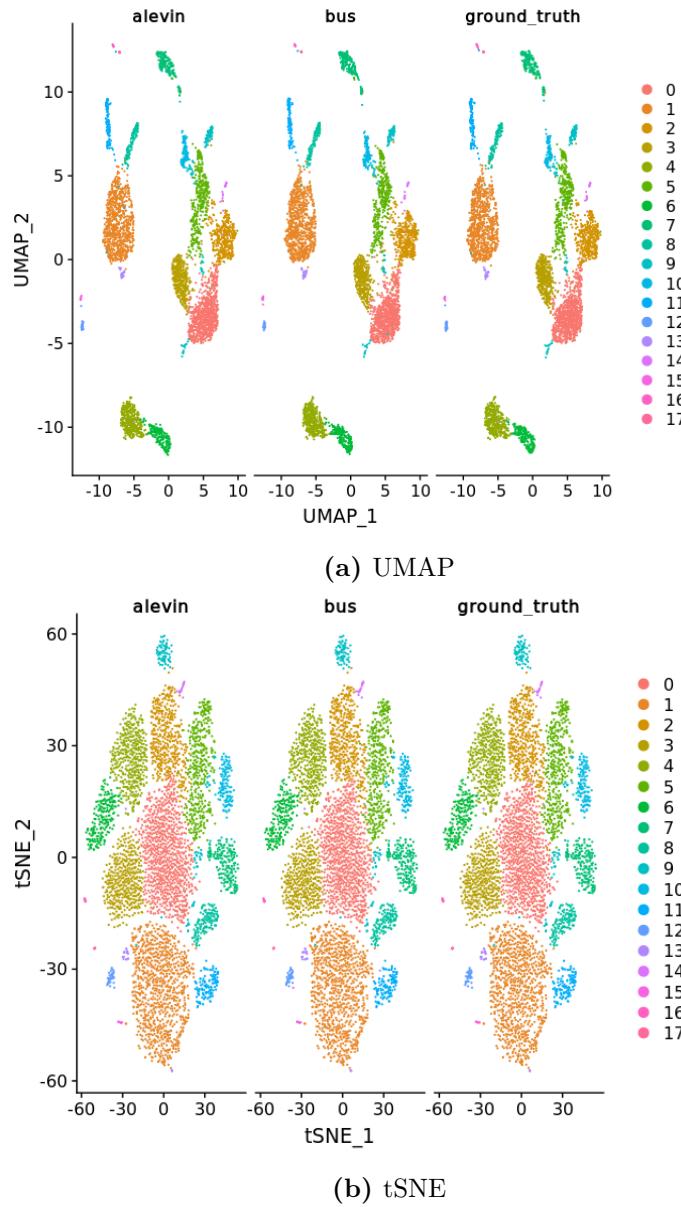

Figure 4.6: Clustering analysis of the simulated data. 18 clusters are present in the ground truth data and Alevin and BUS processed data. Integrated clustering was performed using Seruat 3[211], using both Uniform Manifold Approximation and Projection (UMAP) and t-distributed Stochastic Neighbor Embedding (tSNE) dimension reduction techniques.

performed. Poor quality cells are removed based on numerous parameters. Cells with fewer than a set UMI number (the default is 500), cells with a very low or very high gene count (the default minimum and maximum is 300 and 6000, respectively), and cells with mitochondrial content over a certain ratio (the default is 0.1). This is a user-supervised process, which requires fine-tuning after inspecting

graphs and quality metrics. Parameters can be altered and QC performed again. Following quality control, each sample is clustered individually by Seurat, then all samples are integrated together, by either Harmony or Seurat's SCTransform functionality. The integrated dataset is then annotated by cell type by the packages scClassify, singleR or clustfyr, in combination with a reference dataset or model. Often manual annotation by the user (using known biological markers) is required for finer annotation. The user can then perform further downstream analysis on the annotated integrated dataset, for example differential expression analysis and composition analysis.

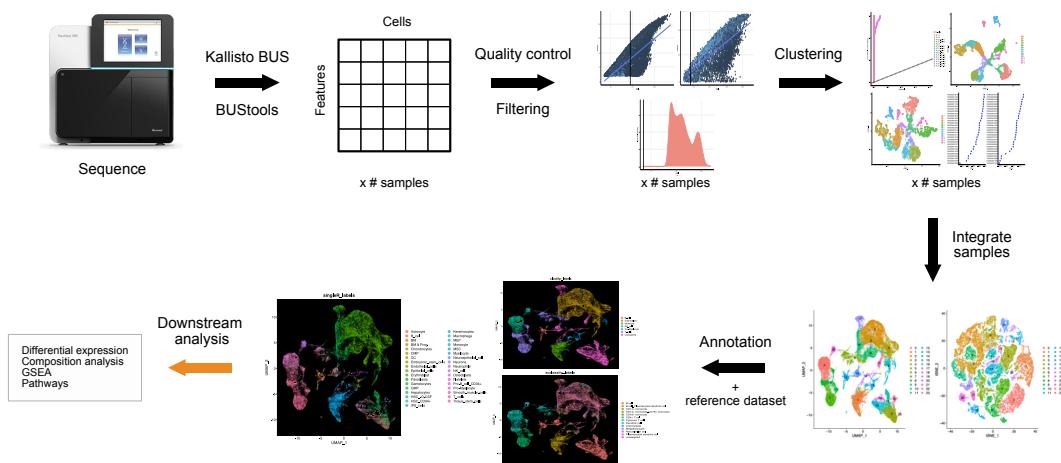

Figure 4.7: Outline of updated scRNA-seq workflow. Each black arrow denotes an independent pipeline. Following sequencing raw FASTQ files are processed by Kallisto BUS and BUStools and cell x gene count matrices are produced for each sample. Quality control (QC) is performed, based on a number of parameter thresholds. QC often requires user supervision to fine-tune the process. Seurat is then used to perform dimensionality reduction techniques and cluster samples individually. Harmony and Seurat are implemented to perform sample integration. The integrated dataset can then be annotated by cell type using packages scClassify, singleR or clustfyr, in combination with a reference dataset or model. The user can then perform further downstream analysis on the dataset, for example differential expression analysis.

4.3 tRNA-seq analysis pipeline

4.3.1 Introduction

Transfer RNAs (tRNAs) are non-coding RNAs that transport amino acids to ribosomes during translation, to implement the genetic code. Most genomes contain

distinct tRNAs for all 61 codons and these are encoded across multiple sites throughout the genome. Sequencing tRNAs is challenging both experimentally and computationally. The main experimental challenges arise from a stable secondary and tertiary structure, making library preparation difficult[213]. Therefore, efficient library preparation methods must be employed to overcome the ridged structure of tRNA, which usually limits the use of standard library prep methods for sequencing[214]. Computationally, the challenges come from overcoming the reverse transcription errors introduced by chemical modifications and accurately mapping reads to tRNA genomic regions, given their multiple genomic loci[215]. Typically, most mapping strategies for gene expression analysis only report read alignments with unique best matches and thus discard reads mapping to tRNA altogether. As a consequence, specialist mapping strategies to accurately map tRNAs have been proposed[216–218]. Specifically, Hoffmann et al. (2018) proposed a two pass mapping strategy that first maps reads to a tRNA masked genome then secondly these unmapped reads are aligned directly to merged tRNA clusters[215].

Computational workflows for small RNA-seq data analysis have been developed previously[219]. However, there are currently a limited number specifically focused on tRNA data analysis. While there have been low-throughput implementations to aid tRNA analysis, such as tDRmapper[216], tRF2Cancer[220], SPORTS1.0[221] and MINTmap[217], there is now a significant unmet requirement for high-throughput approaches to analyse tRNA data. Firstly, it is desirable to have a single pipeline with the flexibility to perform read quality control, mapping to both general genomic and tRNA features, and the ability to perform qualitative and quantitative analyses on tRNAs within a sample. Secondly, with decreasing sequencing costs, it is now common for small RNA-seq libraries to consist of many biological and technical repeats and be sequenced at a much greater depth than mRNA-seq libraries. Thirdly, an appropriate level of detailed reporting output is critical for biological interpretation, which should include appropriate visualisation and publication quality figures.

4.3.2 Pipeline outline

A tRNA analysis pipeline (tRNAAnalysis) was constructed with the aim to meet the demands of tRNA-seq analysis. tRNAAnalysis is written using the Computational Genomics Analysis Toolkit (CGAT) core workflow manager[201], therefore all input fastq files can be processed simultaneously, a detailed log is generated, and the pipeline can be locally run or executed in parallel across a high-performance cluster. tRNAAnalysis implements best practice mapping strategies to allow accurate mapping of tRNA reads[215]. tRNAAnalysis can be installed using Conda and a Docker image is also provided with all of the software and packages installed. Users can therefore use the pipeline without having to install numerous dependencies. Finally, tRNAAnalysis provides a user-friendly html report to visualise qualitative and quantitative outputs. Given that the report is written in R using Rmarkdown, the report is easily extensible and customisable, thus providing a user-friendly approach for visualising the analysis.

The workflow is written predominantly in Python and R, using Ruffus decorators[200], and the CGAT-core workflow manager[201], allowing for automatic cluster submission and parallelisation. The pipeline runs via a single command line interface, providing appropriate default settings, with the option to customise configuration parameters and job resources as required.

The main steps in the analysis are:

- Read pre-processing and quality control
- Mapping of reads
- tRNA quantitative and qualitative analysis
- Downstream analyses and visualisation

Read pre-processing and quality control

tRNAAnalysis accepts raw sequencing data (single-end fastq files) as input and integrates several tools for read quality checking and filtering, including CGAT tools[183], FastQC[222] and FastQ Screen[223]. Given the short length nature of small RNA library preparation, Trimmomatic[224] is used for adapter removal and to filter reads that fall short of quality thresholds. The quality metrics for each sample are then summarised with MultiQC[225].

Mapping of reads

The pre-processed fastq files and a list of gencode annotations are used as the input for mapping. The gencode annotations are supplemented with automatically downloaded RNA repeats (including RNA, tRNA, rRNA, snRNA, srpRNA) from the UCSC database[226]. Firstly, mapping is performed against the genome using Bowtie[227] to obtain a global representation of RNA types. For effective tRNA mapping, tRNAAnalysis implements the best-practice mapping strategy proposed by Hoffmann et al. (2018), in which tRNA loci are masked from the genome and instead, intron-less tRNA precursor sequences are appended as artificial chromosomes[215]. In first-pass mapping, reads that overlap the boundaries of mature tRNAs are extracted. In a subsequent round of mapping, the remaining reads are mapped to a tRNA-masked target genome that is augmented by representative mature tRNA sequences.

tRNA qualitative and quantitative analysis

tRNAAnalysis provides RNA profile analysis that summarises the output of the read alignments mapping to various RNA sequences (e.g. miRNA, piRNA, snoRNA, lncRNA) by counting reads to features with featureCounts[228]. Plots are then generated for each sample, where the positional coverage counts are plotted relative to the exon, upstream and downstream regions of the tRNAs. These plots can then be used to infer the levels of tRNA fragments within a sample. Using the nomenclature first proposed by Selitsky et al. (2015), if the primary tRNA sequence is < 41 nts and ≥ 28 nts, then it is defined as a tRNA-half, while if it is > 14 nts and

< 28 nts then it is defined as a tRNA-fragment[229]. The frequency of read end site relative to the tRNA length is calculated and plotted as bar graphs for each tRNA cluster type. For quantitative measurement of tRNA differences between groups of samples, tRNAnalysis implements DESeq2 to perform differential expression analysis[185]. Finally, given there can be large sequence variations between tRNAs from different tissues as a consequence of RNA modifications[215, 230, 231], any nucleotide misincorporations in the mapped reads are determined. In order to accurately distinguish sequencing errors for true mismatches, `samtools mpileup` is employed to collate summary information in the mapped bam file and then likelihoods of misincorporation are calculated. This information is stored in a bcf file that is then parsed by `bcftools call`, which performs variant calling for each tRNA sequence[232]. The output is then stored as a vcf file and normalised for indels, then filtered for sequencing depth.

Downstream analyses and visualisation

DESeq2 differential expression is performed for sample groups inputted by the user. In order to visualise the output of tRNAnalysis, summary statistics are generated and then reports of these summaries are rendered in html format for visualisation using the Rmarkdown framework. Publication ready reports include figures such as coverage plots, volcano plots of differential expressed tRNAs, tables detailing tRNA modifications and bar graphs of tRNA frequencies. Once these standard reports have been generated, exploratory data analysis can be performed by modifying the Rmarkdown code, allowing for bespoke analysis, tweaking some parameters or to generate more specific publication-quality images.

4.3.3 Simulated data

The accuracy of tRNAnalysis was assessed using simulated read data. Splatter[233] was used to generate a simulated counts matrix, sampling over a negative binomial distribution with two conditions and three replicates. Biostrings[234] was used to generate a fasta file containing sequences from miRNAs, full-length coding mRNAs

and tRNA clusters. The simulated counts matrix from splatter and the mixed RNA-species fasta file were used as input for Polyester[235]. Polyester was ran with an error rate per base of 0.003 to generate simulated RNA-seq read fasta files. Next, CGAT-apps[183] was used to convert the output fasta files into fastq files with uniform quality scores. The simulated fastq files were then used as input for tRNAnalysis to assess its performance.

Performance metrics

The accuracy of tRNAnalysis was evaluated using the simulated data above. Receiver operating characteristic (ROC) curves, precision, accuracy and F1 scores were generated, comparing differential expression between the tRNAnalysis processed simulated data to the known ground truth count matrices. The area under the curve (AUC) was found to be 0.91. The precision was 0.92, recall 0.64 and F1 score 0.76 using a p-value of 0.05, demonstrating a high level of accuracy (Figure 4.8).

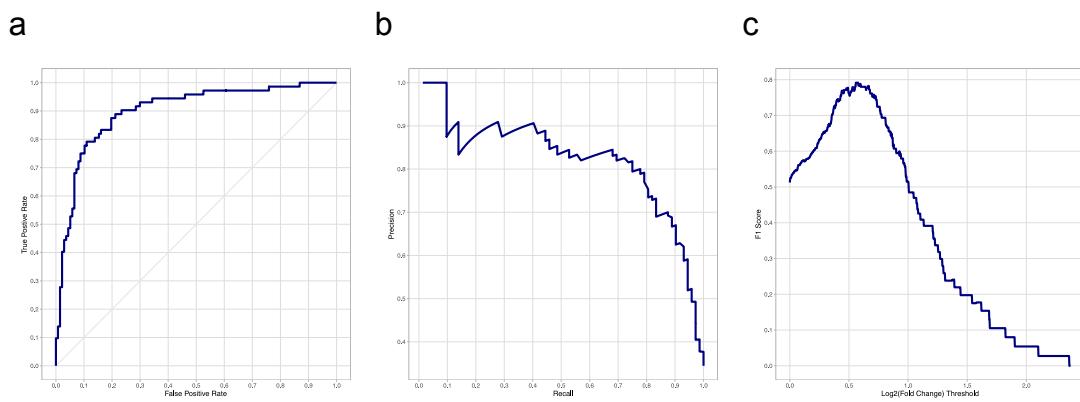

Figure 4.8: tRNAnalysis performance metrics. Comparison of ground truth counts matrix from simulated data vs counts matrix obtained from tRNAnalysis-processed data. Classifying feature differential expression, varying the $\log_2 FC$ threshold. a) Receiver Operator Curve (ROC). Area under the curve (AUC) of 0.91. b) Recall and precision. c) F1 score.

4.4 MM bone marrow classifier

4.4.1 Introduction

To be able to assess myeloma cells from MM patients, bone marrow samples are usually taken from the back of the hip bone. BM aspirates contain red blood cells (erythrocytes), white blood cells (myeloid cells, NK cells, T cells and B cells) and platelets. Traditionally flow cytometry immunophenotyping is used identify the malignant myeloma cells. Flow cytometry (FCM) immunophenotyping uses monoclonal antibodies against an array of antigens expressed on plasma cells, such as CD19, CD20, CD27, CD33, CD38, CD45, CD56, CD117, and CD138[236]. Many scRNA-seq studies use biological markers, FCM immunophenotyping and bead enrichment to sort MM cells and immune cells prior to sequencing. For example, Cohen et al. (2021) sorted MM cells prior to sequencing, they isolated MM cells by magnetic CD138⁺ bead enrichment and stained CD138⁺/CD38⁺ cells with antibodies[237]. Another MM study examined the immune microenvironment of MM only by isolating CD138⁻ and CD45⁺ BM cell fractions, to exclude MM cells[238]. Cells can also be identified after sequencing using computational methods. Numerous automated packages exist to label cell types, however a pre-labelled reference dataset is required to be able to draw comparisons. Currently no MM classifiers or labelled references exist to automate MM scRNA-seq cell identification.

In Chapter 6, two scRNA-seq experiments were performed. For these experiments, no cell sorting took place and the whole bone marrow (WBM) niche was sequenced. Therefore, cell types had to be determined computationally. For annotation of these datasets, references based on healthy tissue were used to inform R annotation packages: clustifyr, scClassify and singleR. As the references originated from healthy tissue, they were unable to label the pathological myeloma cells, and MM cells had to be identified manually using expression of known biological markers. This took considerable time and required significant biological knowledge. An MM classifier or model that could automate cell-type annotation of MM patient BM scRNA-seq samples would save time for researchers and could encourage studies where the

whole BM niche is sequenced, ensuring clonal MM populations lacking CD138 expression are not missed by traditional cell sorting techniques. This could also help remove some of the ambiguity of defining cell clusters.

4.4.2 Classifier building

Using the two scRNA-seq datasets from Chapter 6, cell classifiers were constructed for MM patient BM samples. scClassify's function `train_scClassify` was used to train reference models for scClassify annotation. Log-normalised expression data and a corresponding vector containing manually-defined cell-type annotations were used as input for model training. Three models were generated. The first model was trained using the newly-diagnosed MM patient dataset, the second using the relapsed MM dataset, and the third was trained using both datasets. These models will henceforth be referred to as 'naive', 'relapsed' and 'joint'. The manual annotations used to train the models were much broader than the detailed annotations given in Chapter 6. This was to minimise the number of cells being labelled as 'intermediate' where there was significant overlap between cell subtypes. The broad training annotations can be seen in Figure 4.9.

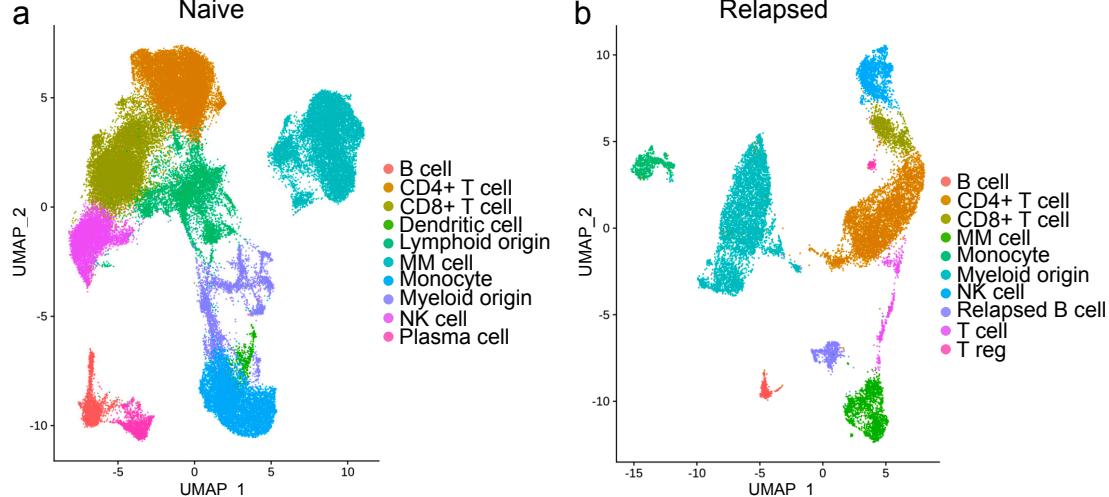

Figure 4.9: Cell type annotation for classifier building. Cell type classifications were made broader than the detailed annotation in given in Chapter 6. a) Newly-diagnosed (naive) MM dataset. b) Relapsed MM dataset.

4.4.3 Classifier testing

In order to test the performance of the MM classifiers, publically available MM scRNA-seq data was downloaded from GEO. The test data comprised one PBMC sample from a relapsed and refractory MM (RRMM) patient, which contained both MM and immune cells (GEO accession number *GSE188632*). The deposited counts matrix was processed using the clustering and annotation modules of the scRNA-seq analysis workflow outlined in Section 4.2.3.

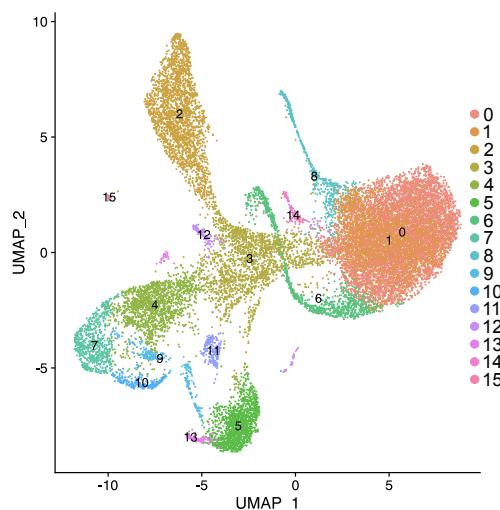

Figure 4.10: Public scRNA-seq data (GEO accession number *GSE188632*) UMAP clustering. 16 distinct cell clusters were identified using Seurat.

16 distinct cell clusters were identified using Seurat (Figure 4.10). Firstly, the data was annotated using scClassify and clustifyr with healthy tissue references. A PBMC model reference was used with scClassify and a HumanCellAtlas (HCA) reference with clustifyr (Figures 4.11a and 4.11b). Both packages labelled the majority of cell clusters as monocytes or other myeloid cell types. Clustifyr-HCA assigned clusters 4, 5, 11 and 13 as NK cells, whilst scClassify-PBMC assigned clusters 5 and 13 as T cells and cluster 11 as NK cells. Clusters 7 and 10 were left unassigned using clustifyr-HCA annotation, whilst clusters 4, 7, 9 and 10 were labelled as B cells by scClassify-PBMC. From the combination of the two annotations it seems like clusters 5 and 13 are T cells, cluster 11 is NK cells, and

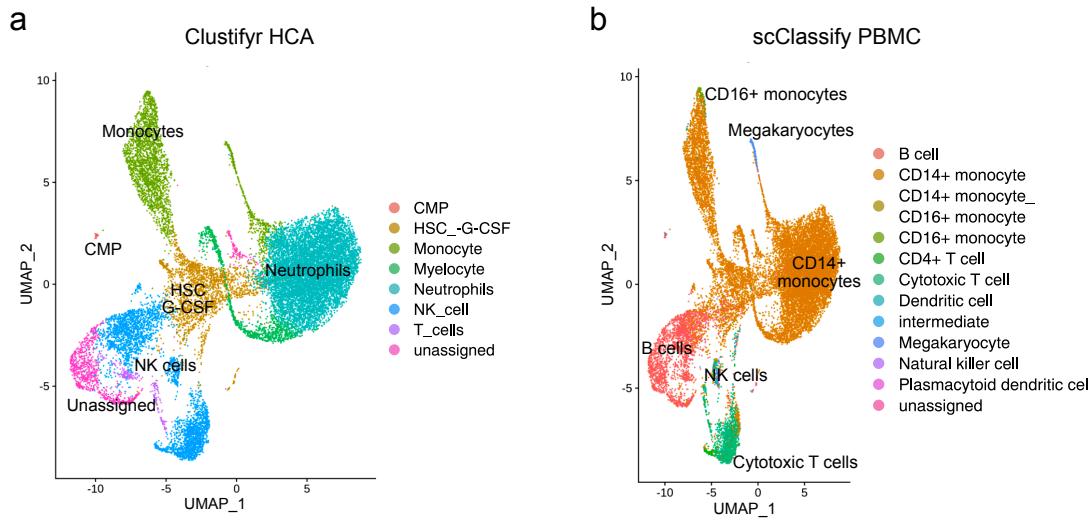

Figure 4.11: Public scRNA-seq data (GEO accession number *GSE188632*) clustering and annotation using references: from healthy tissue. a) Clustifyr annotation performed with the HumanCellAtlas (HCA) reference. b) scClassify annotation performed with the joint PBMC model.

clusters 0, 1, 2, 3, 6, 8, 12 and 14 are myeloid cells. However, from these annotations alone, it is unclear which clusters are the MM cell population.

Next, the scRNA-seq data was annotated using the MM dataset-trained model classifiers generated above (Figure 4.12). Using each model, scClassify identified a number of cells as MM cells (coloured pink in Figure 4.12). The naive model annotation identified the majority of cells in clusters 7, 9 and 10 as MM cells. The relapsed model annotation identified cells in clusters 4, 7, 9 and 10 as MM cells. The joint model annotation mainly identified clusters 7, 9, and 10 as MM cells, and some cells in cluster 4 as MM cells. Additionally, all three models seem to agree with each other and scClassify-PBMC's assignment of non-MM cells, with clusters 5 and 13 being assigned as T cells, cluster 11 as NK cells and the rest of the non-MM cells clusters as myeloid cells.

To assess if the models' MM cell classifications were correct, MM marker expression was examined (Figure 4.13). As discussed in Section 6.2.2, MM cells tend to express or over-express *CD138*, *BCMA*, *IGKC/IGLC2*, *SLAMF7*, and not express or under-express *CD20*, *CD19* and *CD45*. *CD20* and *CD19* were not expressed in this dataset, and *SLAMF7* and *IGLC2* were not expressed very highly in this

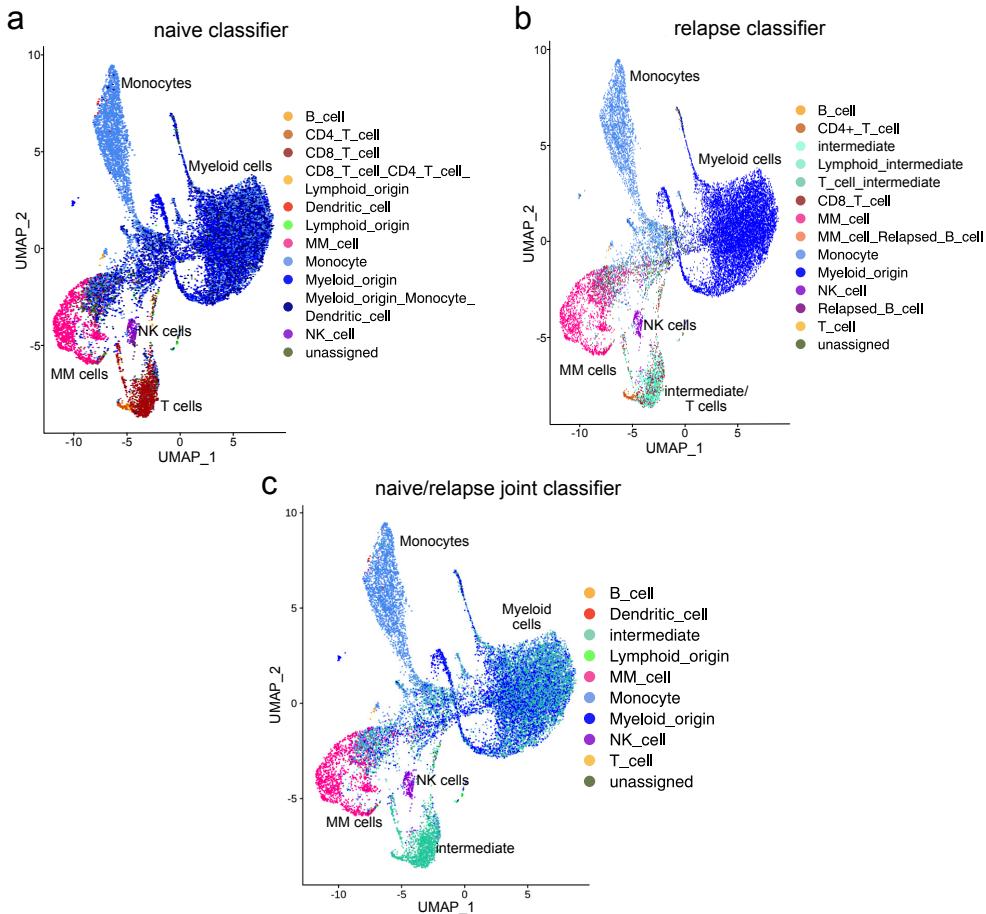

Figure 4.12: scClassify annotation performed on public scRNA-seq data (GEO accession number *GSE188632*) using MM classifier models generated above. a) Newly-diagnosed (naive) MM patient dataset. b) Relapsed MM patient dataset. c) Joint newly-diagnosed/relapsed MM patient dataset.

dataset. *CD138* and *BCMA* were shown to be expressed by clusters 4, 7, 9 and 10. *IGKC* was highly expressed by clusters 4, 7, 9 and 10. Clusters 7, 9 and 10 did not express *CD45*, whilst cluster 4 expressed *CD45*, but to a lesser degree than other clusters. Therefore, it can be concluded that clusters 4, 7, 9 and 10 are likely to be the MM cell population. Clusters 7, 9 and 10 are mainly *CD45*⁻ MM cells, and cluster 4 is mainly comprised of *CD45*⁺ MM cells. Therefore, all three MM model annotations were correct in assigning clusters 7, 9 and 10 as MM cells. There is high confidence, based on the MM gene marker expression knowledge and literature, that the automated annotation using the three MM models correctly assigned clusters 7, 9 and 10 as MM cells. Based on gene expression knowledge, it also seems highly

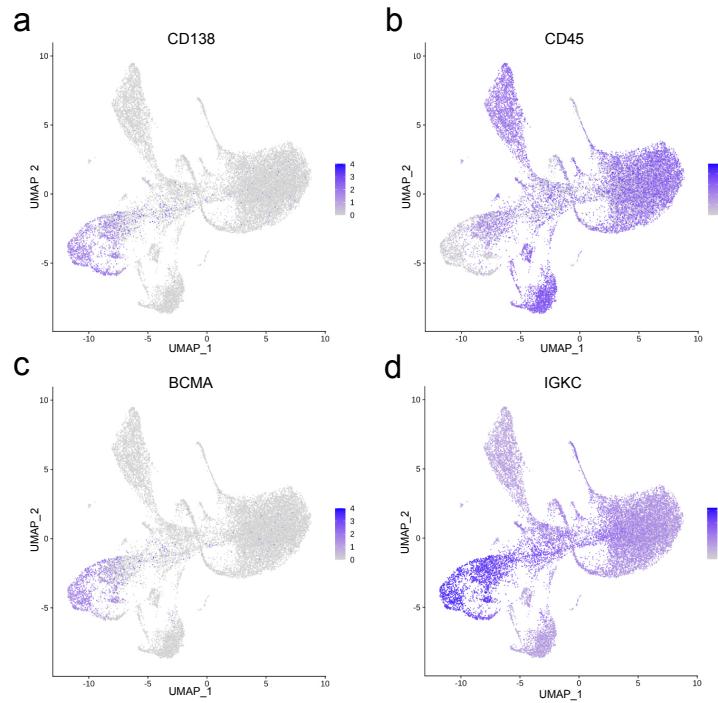

Figure 4.13: Public scRNA-seq data (GEO accession number *GSE188632*) biological MM markers featureplots. a) *CD138* expression- cluster 4, 7, 9 and 10 mainly expressing *CD138*. b) *CD45* expression- clusters 7, 9 and 10 not expressing *CD45*. c) *BCMA* expression- clusters 4, 7, and 9 mainly expressing *BCMA*. d) *IGKC* expression- clusters 4, 7, 9 and 10 have the highest expression of *IGKC*. Expression of *CD19* and *CD20* was not detected in this dataset. There was minimal expression of *SLAMF7* and *IGLC2*.

likely that cluster 4 is also comprised of MM cells. However, the naive and joint models were unable to label many of the cells in this cluster as MM cells, instead labelling them as intermediate cell-types or as myeloid cells.

Next, performance was evaluated quantitatively using ground-truth data. Knowledge on MM gene expression was used to inform the ground truth data, where cells in clusters 4, 7, 9 and 10 were labelled as MM cells, and other clusters as non-MM cells. To quantify each model's accuracy of classifying MM cells, precision, recall and F1 scores were calculated for each of the three models' assignment of cells (as MM vs non-MM) compared to the ground truth results (Figure 4.14). All three models had very high precision values: 0.998, 0.965, 0.987, for the naive, relapsed and joint models, respectively. This reflects a very small false positive rate– the models did not label many non-MM cells as MM cells. The recall score of the models was not as high, indicating there were more false negatives– the models assigned numerous cells in

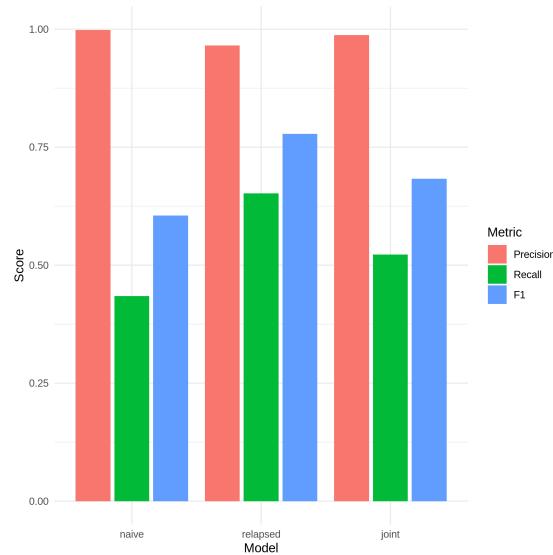

Figure 4.14: MM cell classifier performance. Precision, recall and F1 scores for the three models’ ability to accurately label MM cells; where true positive indicates a cell from the MM clusters (4, 7, 9 and 10) being correctly labelled as ‘MM_cell’ by the model, false positive– a cell from any non-MM cluster being incorrectly assigned the ‘MM_cell’ label, false negative– a cell from one of the MM clusters being incorrectly assigned a label other than ‘MM_cell’.

the MM clusters (4, 7, 9 and 10) as non-MM cells types. The model with the highest F1 score (0.778) was the model generated using the relapsed MM dataset only. This is a good score, indicating that the relapsed model was fairly accurate at classifying MM cells in the test dataset, and demonstrates the effectiveness of using the MM dataset trained models to annotate further MM patient BM scRNA-seq samples.

The GEO dataset originated from a RRMM patient, therefore it is logical that the relapsed model was the most accurate at labelling MM cells. MM patients’ transcriptomes change considerably throughout the course of disease progression and treatment cycles, hence why the naive dataset (although being extremely cell rich- with over 60,000 cells) had the lowest recall score and was not able to classify MM cells as well as the other two models. This should be considered when using the MM classifiers in future. Appropriate classifiers should be applied to scRNA-seq datasets, such that the naive model is used for newly-diagnosed MM patient data and the relapsed model is used for RRMM patient data. In addition, as shown in the joint model, scClassify models can be trained using multiple patients or scRNA-

seq experiments. As more MM scRNA-seq experiments (including the full BM niche) are performed and the data made publically available, more comprehensive models can be generated, with further MM scRNA-seq annotations added to the training set. More myeloma patient samples would make the classifiers more accurately represent the heterogeneity seen in MM, and therefore more accurately annotate future MM datasets.

4.5 Discussion

Before the advent of NGS, the bottleneck in omics experiments was the technology available, which severely limited data acquisition. For example, the Human Genome Project (HGP) was initiated in 1990 and was projected to be completed by 2005 (a 15 year effort). Initially the HGP relied on low-throughput Sanger sequencing. However, the advent of NGS sequencing significantly increased the throughput and led to the completion of the HGP two years ahead of time. Since the use of NGS and TGS technologies— with their higher throughput compared to traditional first-gen techniques— the bottleneck of omics experiments has shifted to data processing and data discovery. Over the last two decades, numerous computational methods and tools have been invented to relieve the strain of data processing times.

The ever-increasing volumes of omics-data require data-processing pipelines/workflows that are robust, quick and efficient, whilst possessing the scientific rigour that allows for consistent and fully reproducible analysis of results. Robust and reproducible genomic workflows allow for confidence in interpreting results in meaningful biological context.

The CGAT framework was used to construct computational pipelines for data processing and extraction of biologically meaningful statistical analyses, summaries and visualisations from input data. The CGAT-framework was chosen as the base for the computational pipelines in this work because: CGAT-core can handle parallelisation across HPC clusters, it is integrated with the use of Conda environments, it allows for parameterisation of pipelines, it is open-source, and it records detailed logs of progress. Additionally, numerous tools for specialised

bioinformatics tasks are available via CGAT Apps[183] (a collection of scripts to aid the analysis of high-throughput sequencing data). The large size of omics data means that many computational biologists use HPC clusters to analyse their data, to reduce computing time. Moreover, most cluster users do not have sudo access rights, therefore must use package and virtual environment managers. Conda integration was an important factor for the pipeline-framework, as other package managers, such as Pip, are mainly for Python package installation, whereas Conda is a cross-platform environment manager. Many bioinformatic tools are written in R and are easily available on the Bioconda channel of Conda. Logging of pipeline progress allows for easy reproducibility of results. CGAT pipelines are built on top of Ruffus workflow management. In a review of bioinformatic pipeline frameworks, Ruffus was rated pipeline framework with the highest ease of development, such that it requires the least effort to develop new workflows[239]. This further adds to its appeal, as creators require less time and effort to write new workflows, but also users should be able to easily debug errors themselves and adapt the workflows as they see fit.

Using the CGAT framework, analysis pipelines were constructed for dscRNA-seq pseudoalignment analysis, tRNA-seq analysis, scRNA velocity analysis and virus detection in scRNA-seq data.

4.5.1 Benchmarks

Benchmarks were conducted to assess the performance of several pipelines. A combination of simulated and real data was used to assess performance. Simulated data allows comparison of the output of a given method to a known ‘ground-truth’. This is a key strength of using simulated data as you can directly compare to known scores or values, and quantitatively assess the accuracy of a method. For transcriptomic data, often the known ground truth data is a counts matrix, either gene x sample for bulk methods or gene x cell for single-cell methods. Additionally, simulated data can be used as lightweight data for testing, as opposed to using large real-world data. However, using simulated data poses several limitations. The model under which the simulated data were generated can alter the results of the

benchmark and favour certain methods over others. For example, a benchmark was performed for 12 different scRNA-seq simulation methods, across 35 different datasets[240]. The study observed differing results for each method across four evaluative categories (data property estimation, biological signals, scalability and applicability), indicating that the method of simulating data can affect the performance of a model in a benchmark[240]. Often authors of a new method or tool perform a benchmark themselves, boasting its superiority over previous methods, without using a systematic assessment procedure (tralling numerous simulated datasets, with varying parameter values), this can lead to biases in their published results—this is known as the self-assessment trap[241].

Secondly, simulated data is unable to capture true experimental variability, and will always be less complex than real-world data[241]. It has been shown that various scRNA-seq data simulation methods are unable to reflect the level of heterogeneity seen in a population due to inter-patient variability[240]. Considering the pipeline generated in this work will be primarily used to analyse MM data, the benchmark has done little to support that it will be appropriate to infer results from heterogeneous MM patients.

Thirdly, transcriptome simulation methods are unable to simulate reads from intronic and intergenic regions of the genome, or transcripts that are not part of the annotation used to generate the reads. This complexity is present in experimental datasets.

4.5.2 scRNA-seq analysis benchmark

MM is an extremely heterogeneous disease, with numerous interactions with the surrounding immune microenvironment. Therefore, to best examine MM and the effects of therapeutics, single-cell techniques are required, including scRNA-seq to study the transcriptome at the single-cell level. To be able to interpret results from scRNA-seq data, a robust and reproducible scRNA-seq analysis pipeline was required.

It has previously been shown using simulated data, that pseudoalignment/lightweight mapping strategies demonstrate similar accuracy to traditional mapping strategies such as STAR and Bowtie2, yet provide massive improvements in computing time and memory usage. Therefore, it was decided that only lightweight mapping strategies would be implemented in the scRNA-seq analysis pipeline. The pipeline was written with the ability for the user to choose either Kallisto BUStools or Salmon Alevin for pseudoalignment. However, for consistency in the lab's analysis workflow, only one tool would be used for all future scRNA-seq data. To determine which lightweight mapping method to use, a benchmark was conducted using simulated scRNA seq reads. From this benchmark Kallisto BUS/BUStools was determined more accurate and faster than Salmon Alevin. This result has been confirmed by subsequent benchmarks[208, 242, 243].

More recently, the Patro lab have introduced a reimplementation of Salmon Alevin, called Salmon-Alevin-Fry (SAF)[244]. SAF outputs a file similar to a BUS file, with the aim of quicker compute time and less memory usage. The Pachter lab (the lab responsible for Kallisto) performed a benchmark of the new SAF framework against Kallisto BUStools[245]. To avoid the self-assessment trap, both programmes were ran using the developer recommended settings, and compared over many datasets, across a variety of organisms and tissues. The group used real-world data to compare the methods. They achieved this by processing the same experimental reads with both SAF and Kallisto BUStools and then combining the SAF processed cells and Kallisto BUStools processed cells together into one dataset. After dimensionality reduction, the distance between identical ('doppelganger') cells either processed by SAF or BUS was examined and compared to the next nearest cell. The group found that gene expression differences between SAF and Kallisto were negligible for clustering analysis and irrelevant for downstream analysis. They also found that even with the updated SAF framework, Salmon-Alevin-Fry remained significantly slower and required more memory to run than Kallisto BUStools. This confirms the results of the benchmark conducted in this work and the subsequent decision to use Kallisto BUStools as the lightweight mapper of choice for scRNA-seq analysis.

The benchmark performed in this work used precision, recall and F1 scores to assess accuracy. These scores use binary classifications, therefore the benchmark only looked at the accuracy of ‘Expressed’ vs ‘Not expressed’ for every gene, across every cell. This was considered an appropriate measure of accuracy, as the fraction of zeros (cells not expressing a given gene) in a dscRNA-seq experiment is extremely high, sometimes exceeding 90%[246]. However, the benchmark does not give any information about abundance quantification accuracy. As such, in a scenario where one of the methods outputted a count value of 1 vs another method outputting a count of 1000 would be considered as the same by the benchmark (i.e. expressed), even though they are clearly very different counts biologically. As such, a scenario in which one method outputted a count of 1, and another method outputted a count of 1000 for a given gene, the benchmark would consider this the same result for both methods (i.e. gene expressed), even though they are clearly very different counts biologically. Srivastava et al. (2020) investigated the transcript abundance quantification performance of traditional mapping and alignment strategies Bowtie2 and STAR compared to the pseudoalignment method Salmon[247]. The group calculated Spearman correlation of quantification estimates by each alignment method compared to Polyester simulated scRNA-seq ground-truth data.

To demonstrate the application of the pipeline and its effectiveness for MM data, a more comprehensive benchmark could be performed by implementing some of the strategies summarised above. For simulated data: as well as assessing accuracy of expression vs no expression, gene abundance quantification accuracy should be examined using Spearman correlation statistics. Real world data should also be included, to assess how methods perform with added experimental complexity and heterogeneity. Since no ground-truth data is available, it becomes more challenging to analyse accuracy. The strategy implemented in [245] could be generalised to include all traditional mapping and lightweight mapping techniques. This could be performed by processing a real-world dataset using the numerous mapping/alignment methods, then combining them together into one counts dataset, so that for each biological cell there are numerous ‘doppelganger’ cells each processed by a different

method. Following dimensionality reduction of this matrix, you would expect the ‘doppelganger’ cells originating from the same biological cell to cluster together. L1 distances from the centroid of these clusters could then be calculated for all of the methods, across every cell in the dataset, to give an overall score for each method and to see how much each method agrees with one another. This strategy could be implemented for real-world MM data, to ensure the alignment methods chosen are appropriate to analyse MM patient data.

4.5.3 MM classifier

The MM classifier generated in this chapter allows for automated identification of MM cells in scRNA-seq datasets, and removes part of the data processing bottleneck of data analysis. The MM classifiers implement a supervised machine learning (ML) algorithm (k-nearest neighbour model), to classify cell types. The classifiers performed well on test MM experimental scRNA-seq data. There was high agreement between classifier MM identification and gene expression-based cell type identification. An independent dataset was used for testing, originating from a different patient, and performed in a separate experiment. However, the ‘ground-truth’ data was defined by me based on cell type classifications using gene expression data of the test data. The classifiers were trained on MM scRNA-seq data, also labelled by me using gene expression data. Therefore, this might influence the agreement between the classifier outcome and ground truth data.

The performance of the classifier is dependent on the data used to train the model. The classifier generated in this work is based on three experiments, consisting of BM samples from four patients, two of whom were newly-diagnosed MM patients, and two relapsed patients, totalling approximately 80,000 cells (Chapter 6- Table 6.1). These are very cell-rich datasets, however due to the heterogeneity seen in MM, the classifiers would probably benefit from more MM scRNA-seq datasets being incorporated in the training of the models. Additionally, the labels outputted by the classifiers are dependent on the initial assignment of cell types on the training data

by the user. Therefore, accurate cell type assignment must be made on the initial training set, to ensure correct identification by the classifier on the query dataset.

Cell sorting vs whole bone marrow niche

During normal B cell development into plasma cells, cells start expressing CD138. In the bone marrow, CD138 is a specific surface antigen for plasma cells and MM cells[248]. The typical approach for isolating plasma cells is to use CD138⁺ magnetic selection; this can enrich plasma cells around 100 times[249]. This is useful to offset the high costs of single-cell sequencing, so that a high cell count and read depth can be achieved for MM cells, without sequencing other immune cells, which are often of low importance to researchers. However, previous studies of MM cell lines and clinical MM samples have shown a small population of MM cells lack CD138 expression[250], therefore anti-CD138 antibodies will recognise only a sub-population of MM cells. CD138 also has a fast turnover on the cell membrane, and is constitutively shed on cultured cells and apoptotic cells[249]. Passaging in cell culture, sample processing and drug treatment can induce rapid apoptosis in primary myeloma cells, leading to CD138 shedding. Furthermore, CD138⁻ MM cells have been reported to have more proliferative potential than CD138⁺ MM cells and that they play an important role in regulating bone marrow stromal cells[251, 252]. Matsui et al. (2004) reported the existence of CD138⁻ MM ‘stem cells’, which had greater clonogenic potential than CD138⁺ MM cells and phenotypically resembled postgerminal center B cells[250]. A decrease in CD138 expression has also been observed during the course of treatment in some MM patients[248]. Therefore, by separating cells based on CD138 expression, information on a whole subpopulation of MM cells may be lost. Results will be skewed towards CD138⁺ MM cells. Due to the large heterogeneity seen in MM, and the role of MRD and clonal evolution in acquired-drug resistance— the entire MM cell population must be investigated to get an accurate picture of the whole MM landscape.

Bansal et al. (2021) highlighted issues with sorting PCs using CD138, beyond the scope of losing heterogeneous CD138⁻ MM populations. The group investigated the

impact of CD138⁺ magnetic bead-based selection compared to WBM processing on BM plasma cell surface markers using FCM[249]. They found that CD138⁺ selection of PCs appears to change important markers on the PCs, such as substantial loss of expression of CD71, CD11b, CD11a, CD69 and CD49e, and also almost a complete loss of CD45⁺ cells in half of cases. From the study it was not clear if this phenotypic change of PCs was due to antigen loss from the process of selection or if subsets of cells were eliminated/ preferentially selected. For DNA and RNA-based studies (like scRNA-seq) it is very concerning that CD138⁺ selection could preferentially select for a subset of cells, as this would mean further heterogeneity is being lost and results are being skewed to a subset of MM cells. CD138⁺ selection vs WBM methodology should be investigated using scRNA-seq to ascertain if the phenotypic changes of PCs after CD138⁺ selection seen in flow cytometry reflect antigen loss or selection of a subset of cells.

Considering the above limitations regarding CD138 expression and selection, together with the established interactions between MM cells and their surrounding immune microenvironment, it seems sequencing the whole bone marrow niche should be the preferred method for MM scRNA-seq studies. Despite this, the vast majority of MM scRNA-seq studies sort cells prior to library preparation. Sequencing the WBM niche is more expensive than sequencing isolated PCs (if maintaining a good read depth and high cell count), it also requires more time, effort and skill to process the data– for example assigning cell types to clusters. The MM classifier created in this work automates cell type classification and helps address the additional computational effort required for MM WBM scRNA-seq. All future MM scRNA-seq data produced by the Oppermann lab will use the MM classifiers to assign cell types to clusters. Hopefully more external MM researchers will start adopting the WBM method for scRNA-seq. As more researchers perform MM WBM scRNA-seq experiments and make the resulting data publically available, MM classifiers can be improved further with more data from heterogeneous patients. The relapsed MM classifier created in this work is hosted publically on Github

(https://github.com/annajbott/MM_classifier), along with code to generate new classifiers, so that other researchers can use this tool.

Further, this approach could be expanded to create MM classifiers not only to identify and label MM and immune cell types, but to also predict clinical characteristics in datasets, such as risk, response to certain therapeutics or drug resistance status. Previously, machine learning (ML) approaches have been applied to bulk RNA sequencing profiles from 53 MM patients to create a classifier to predict good and poor responders to certain treatment regimens[253]. ML classifiers based on scRNA-seq datasets would likely have more power and stronger predictive capabilities than classifiers built using bulk RNA-seq data, due to the underlying heterogeneity of the patient data and the high dimensionality of scRNA-seq data. In recent years there have been applications of scRNA-seq based ML predictions and classifications in cancer. scRNA-seq datasets have been used for binary and pan cancer classification of certain breast and skin cancers[254]. ML techniques have also been applied to scRNA-seq datasets to predict drug resistance and characterise inter- and intra-tumour heterogeneity in MM[255, 256]. However, these studies looked at CD138⁺ PCs only and did not consider the immune microenvironment. I expect there to be numerous applications of ML and deep learning methods to MM scRNA-seq data in the coming years, as the price of single-cell sequencing lowers and more computational biologists move into the field. However, I do believe the WBM niche should be included in MM classifiers and predictive tools to fully utilise all knowledge available and capture as many MM features as possible to inform the underlying models.

5

Bulk RNA-seq analysis of ProRS inhibitors

5.1 Introduction

Although MM treatment has improved significantly in the last 20 years, MM remains an incurable disease. MM patients relapse and become resistant to drugs with which they have previously been treated. Therefore, research into novel therapeutics that can overcome multi-drug resistance and can be used to treat relapsed patients is of great importance.

New analogues of febrifugine derivatives are being actively researched for the treatment of many diseases, including numerous cancers[164, 165]. Febrifugine is the biologically active component of the herb *Dichroa febrifuga*, which is considered one of the fundamental herbs in traditional Chinese medicine[161]. Febrifugine is a quinazolinone alkaloid, which has been shown to possess strong anti-malarial properties. One such febrifugine derivative, halofuginone (HF), has previously been shown to inhibit TH₁₇ cell differentiation, by activating the amino acid starvation response (AAR)[169]. Halofuginone inhibits the ProRS activity of the enzyme glutamyl-prolyl-tRNA synthetase (EPRS)[170]. EPRS is a bifunctional aminoacyl-tRNA synthetase (aaRS) and catalyses the aminoacylation of glutamic acid and proline tRNA species (such that it charges its cognate tRNAs with glutamic acid and proline). Halofuginone and febrifugine compete with proline at the prolyl-tRNA synthetase active site of EPRS, specifically targeting utilisation of proline during

translation[170]. This results in an accumulation of uncharged tRNA^{Pro}s, giving the same cellular environment as if the cell were proline deficient, triggering the AAR to respond to the apparent proline deprived state.

aaRSs are essential in protein synthesis. Human cancer cells often have an increased rate of protein synthesis, this is especially true in MM cells, which create huge amounts of non-functional paraprotein, and are therefore more reliant on aaRS activity. As discussed in Chapter 2, HF has previously shown anti-MM activity in vitro and in vivo[115]. HF induced cytotoxicity and apoptosis in numerous MM cell-lines and primary MM cells. HF was also shown to inhibit MM growth and prolong survival in a mouse xenograft MM model. However, the mechanism by which HF exerted its affect was not elucidated, and it is not clear if the AAR plays a role in HF's effectiveness in MM.

It has also been shown that HF's anti-MM effect can be reduced in the presence of excessive proline[115]. Proline is abundant in many tumours, which may result from upregulated matrix metalloproteinases (MMPs) degrading collagen in the extracellular matrix (ECM), and/or increased conversion of glutamine to proline compared to normal cells[173]. Elevated proline levels have been noted in the BM of MM patients[257]. This increased proline concentration means that HF has a limited efficacy especially in situations of increased proline levels. This has ben observed as mechanism of HF resistance, for example in *Plasmodium falciparum*[258].

Recently, the Mazitschek group at Mass General Hospital, have synthesized compounds which target the ProRS site of EPRS. One such example, NCP26 (Figure 5.1b), further developed from an initial hit (NCP22)[181], does not compete with proline for the active site of ProRS, unlike febrifugine and halofuginone. NCP26 binds to the ATP binding site of ProRS, inhibiting utilization of ATP. Aminoacylation is an ATP-dependent process, therefore blocking ATP binding inhibits this process, and also leads to an accumulation of uncharged tRNA^{Pro}s. These molecules are attractive targets due to their mechanism of action and potentially alleviate some of the issues associated with HF treatment.

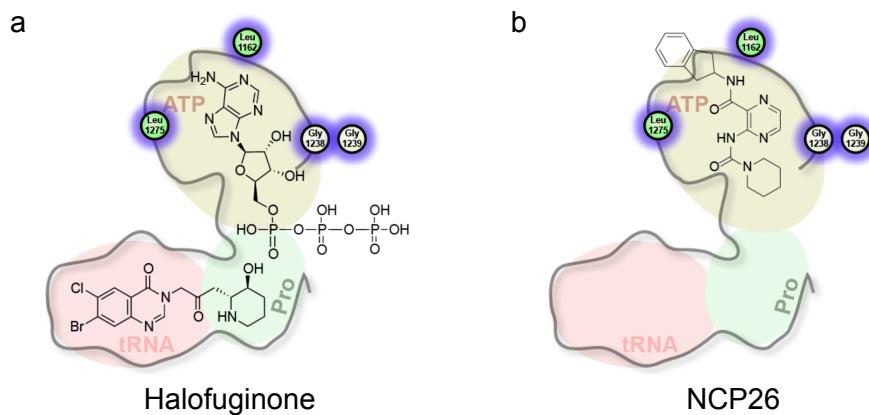

Figure 5.1: Diagrams of halofuginone/MAZ1392 (a) and NCP26 (b) and their chemical structures. Halofuginone is an ATP dependent, proline and tRNA competitive ProRS inhibitor. NCP26 is an ATP competitive and proline uncompetitive ProRS inhibitor. Aminoacylation is an ATP-dependent process, requiring ATP to activate amino acids. Figure by Ralph Mazitschek.

This chapter uses MM cell-line models to assess the effectiveness of these ProRS inhibitors and uses bulk RNA-seq to capture the transcriptional landscape following ProRS inhibitor treatment and ProRS inhibitor resistance.

5.2 Cell-based assay results

5.2.1 Cell line validation

In this chapter, two MM cell lines were used. Low-passage-number AMO-1 (henceforth referred to as wild type; WT) cells, which are sensitive to various MM treatments, and carfilzomib-resistant L363 (henceforth referred to as CFZr) cells. Dose response curves for the two cell lines treated with proteasome inhibitors (PIs), carfilzomib and bortezomib, were generated to confirm the PI-resistance of CFZr cells and PI-sensitivity of WT cells (Figure 5.2). The IC₅₀s for AMO-1

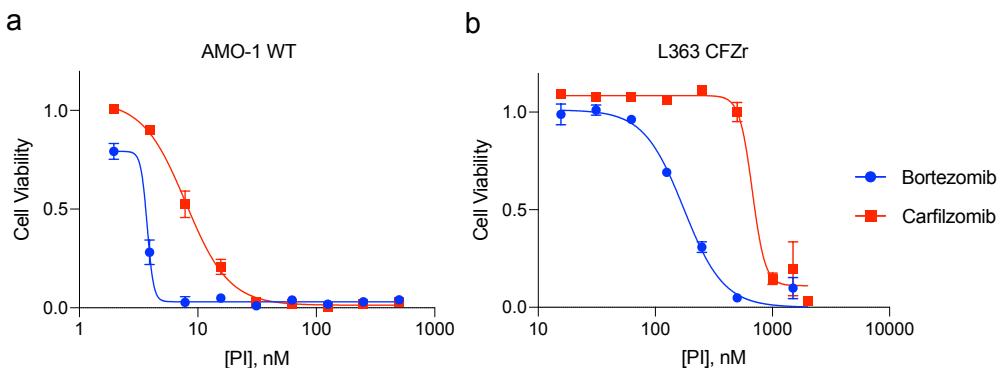

Figure 5.2: Multiple myeloma (MM) cell lines, AMO-1 (WT) and carfilzomib-resistant L363 CFZr, treated with carfilzomib (CFZ) and bortezomib (BTZ). MM cell lines were treated for 48 hours with a range of concentrations (approximately 1nM-1μM) of proteasome inhibitors (PI). a) AMO-1 (WT cells). b) Carfilzomib-resistant L363 cells (CFZr).

(WT) cells were approximately 3.74nM and 7.93nM for bortezomib and carfilzomib, respectively. For L363 CFZr cells, the IC₅₀s were approximately 174.8nM and 673nM for bortezomib and carfilzomib, respectively. This confirms that WT cells are sensitive to proteasome inhibition, with IC₅₀s in the low nanomolar range. It also demonstrates that CFZr cells are much more resistant to proteasome inhibition, with the IC₅₀ of CFZr cells almost 85 times higher than WT cells for carfilzomib.

As expected, CFZr cells are more resistant to carfilzomib treatment than bortezomib treatment, as their resistance was developed by exposure to increasing carfilzomib concentrations. However, it is clear that some cross-resistance to bortezomib is also acquired (the IC₅₀ for BTZ treatment is 46 times greater in CFZr

cells than WT cells.) This is likely due to the similar mechanism of actions of the two drugs, conferring resistance to bortezomib treatment too. It could also be in part due to increased expression of general multi-drug resistant genes, such as ATP Binding Cassette Subfamily B Member 1 (*ABCB1*). This mimics clinical MM well, as patients are treated with carfilzomib as a second-line treatment, once they have already been treated with bortezomib, developed some resistance to it and relapsed.

Together, this validates that AMO-1 (WT) cells and L363 CFZr cells are suitable cell models for PI-sensitive and PI-resistant MM.

5.2.2 Halofuginone and NCP26 are cytotoxic to drug sensitive and drug resistant MM cell lines in a dose-dependent manner

The effect of the ProRS inhibitors NCP22, NCP26, MAZ1805 (halofuginol) and MAZ1392 (halofuginone; HF) on cell viability was investigated using the MM cell lines AMO-1 and L363 CFZr. The cell lines were treated with a range of concentrations of each compound (3.9nM- 1 μ M). Cell viability was assessed using presto blue assays (Section 3.3.2), and dose response curves were generated (Figures 5.3a and 5.3c). Halofuginone and NCP26 reduced cell viability of PI-sensitive AMO-1 cells and carfilzomib resistant L363 cells in a dose-dependent fashion. For this concentration range, MAZ1805 and NCP22 seemed to have little effect on cell viability of WT or CFZr cells, and IC₅₀ values were unable to be calculated. Halofuginone was found to be more potent than NCP26.

For WT AMO-1 cells, halofuginone had an IC₅₀ of 141.8nM and NCP26 an IC₅₀ of 502nM. For CFZr cells, halofuginone had an IC₅₀ of 1185nM and NCP26's IC₅₀ was ambiguous, a higher stock concentration would be required for calculation. Figure 5.3b and 5.3d show the proportion of viable cells following 48 hours of treatment of the ProRS inhibitors. WT AMO-1 cells were found to be more sensitive to NCP26 and halofuginone treatment than carfilzomib resistant L363 cells. This may indicate some acquired cross-resistance built up from carfilzomib exposure or inherent resistance in the L363 cell line over the AMO-1 cell line.

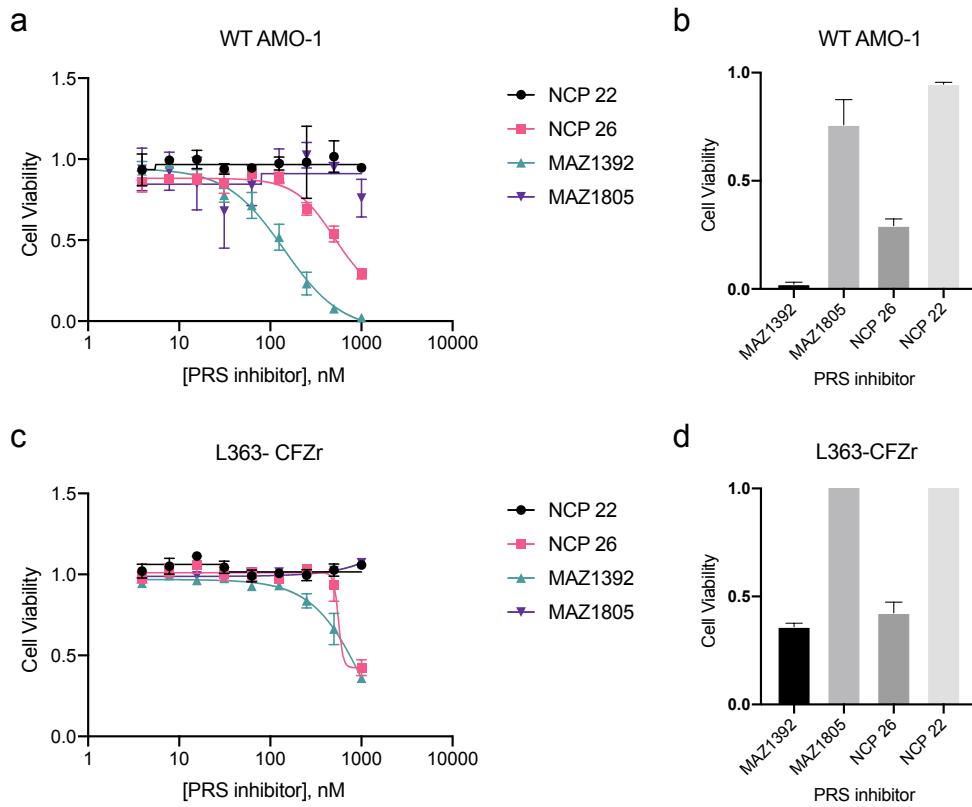

Figure 5.3: Viability of MM cell lines treated with ProRS inhibitors- MAZ1392 (halofuginone), MAZ1805, NCP26 and NCP22. MM cell lines were treated for 48 hours with a range of concentrations (3.91nM-1μM) of ProRS inhibitors. a) and c) Dose response curves. a and b) WT AMO-1 cells. c) and d) Carfilzomib resistant L363 cells. b) and d) Proportion of cells viable after 48 hours of 1μM treatment with each agent.

5.2.3 Carfilzomib and NCP26 have an additive or mild antagonistic effect

Drug combinations have proved effective in MM in recent years, for example the combination of bortezomib, lenalidomide, and dexamethasone (VRd). Drugs are often used in combination so that outcomes are improved (synergistic efficacy) or to reduce off-target effects and toxicity by minimizing the doses of the drugs (synergistic potency)[259].

To assess if NCP26 and carfilzomib work together synergistically, AMO-1 cells were treated with varying concentrations of NCP26 and carfilzomib for 72 hours, then presto blue assays were performed to determine cell viability. As shown by dose response curves in Figure 5.4a and the response matrix in Figure 5.4b, NCP26 and

carfilzomib elicit a stronger cytotoxic effect together than each agent individually. SynergyFinder[260] was used to calculate the compounds' synergy scores (-4.66 ZIP; -4.18 Loewe; -5.53 Bliss). From these values it is unlikely that NCP26 and carfilzomib work together synergistically. NCP26 and carfilzomib seem to have an additive effect together, or slight antagonistic effect. This reflects a previous result

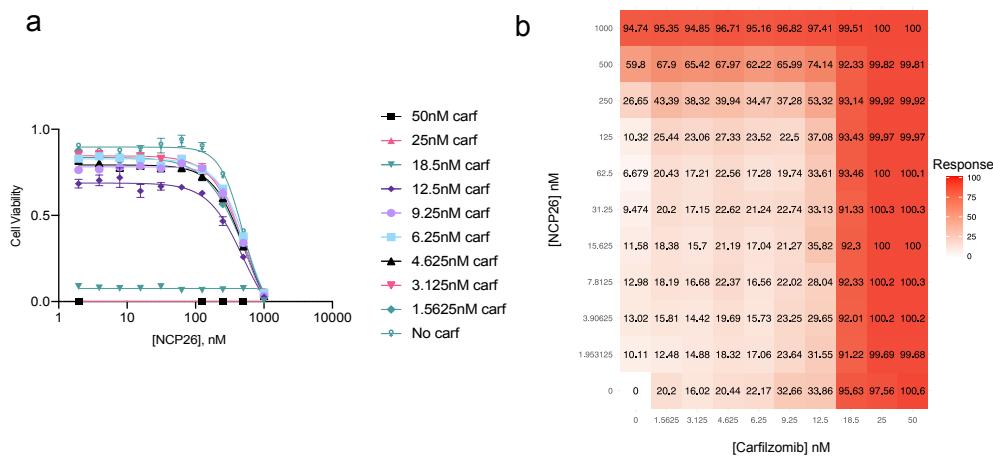

Figure 5.4: Investigating synergy between NCP26 and carfilzomib. AMO-1 cells were treated with varying concentration combinations of NCP26 and carfilzomib for 72 hours, then cell viability was determined using presto blue assays. a) Dose response curves for NCP26 with different carfilzomib concentrations. b) Matrix view of NCP26 and carfilzomib concentration responses.

where HF demonstrated moderate antagonism with the bortezomib[115]. This may indicate that HF and NCP26 may not work very well in combination with proteasome inhibitors in MM. Although, the group only used a single concentration of BTZ (5nM) and 3 concentrations of HF (25, 50 and 100nM). This limits their ability to determine synergy, as only very few concentration combinations were tested. In the same study, HF was shown to exhibit moderate synergistic cytotoxicity with other anti-MM agents, including the IMiD lenalidomide and the corticosteroid dexamethasone. This might demonstrate the potential of using ProRS inhibitors in combination with IMiDs and corticosteroids, perhaps in place of proteasome inhibitors, once PIs become less effective for MM patients. Indeed, with the promising results in Figure 5.3d, HF and NCP26 have shown cytotoxicity against PI-resistant cells and therefore hint towards being an effective agent against relapsed and PI-resistant MM.

5.3 ProRS inhibitor treatment bulk RNA-seq

5.3.1 Experiment overview

The transcriptome of drug-sensitive and PI-resistant MM cells following treatment with four ProRS inhibitors was investigated using bulk RNA-seq. PI-sensitive WT AMO-1 cells and carfilzomib resistant L363 cells (CFZr) were used. Cells were treated for 6 and 24 hours with a DMSO control, or 1 μ M of a ProRS inhibitor (MAZ1392 [halofuginone], NCP26, NCP22 and MAZ1805 (halofuginol)), or 100nM carfilzomib (AMO-1 WT cells only). CFZr cells were treated in the presence of 100nM carfilzomib. Samples were prepared for sequencing as in Section 3.4. The computational workflow for bulk RNA-seq analysis is outlined in Section 3.6.1.

5.3.2 Clustering

Figure 5.5 shows clustering analysis. Figure 5.5a and 5.5b show that the samples distinctly separate into their respective cell types, and this makes up the majority (69%) of the variance in the dataset. Therefore, the different cell types (WT and CFZr) were separated and analysed individually (Figures 5.5c-f).

The less active compounds (as demonstrated by ProRS inhibitor dose response curves; Figure 5.3), MAZ1805 and NCP22, cluster closely with the DMSO-treated controls. The more active inhibitors, NCP26 and halofuginone, cluster separately from DMSO controls and less active inhibitors, indicating they have elicited a stronger transcriptional response. At 6 hours NCP26 and halofuginone cluster closely together. At 24 hours NCP26 and halofuginone separate more. This may suggest a distinction in their mechanism of action, or this could just be reflecting the differences in their potency.

In WT cells, carfilzomib clusters separately from DMSO and the less active inhibitors. At 6 hours, carfilzomib samples are very separate from the NCP26 and halofuginone cluster, but they cluster together more closely at 24 hours. This could suggest an initial difference in mechanism of action and transcriptional response

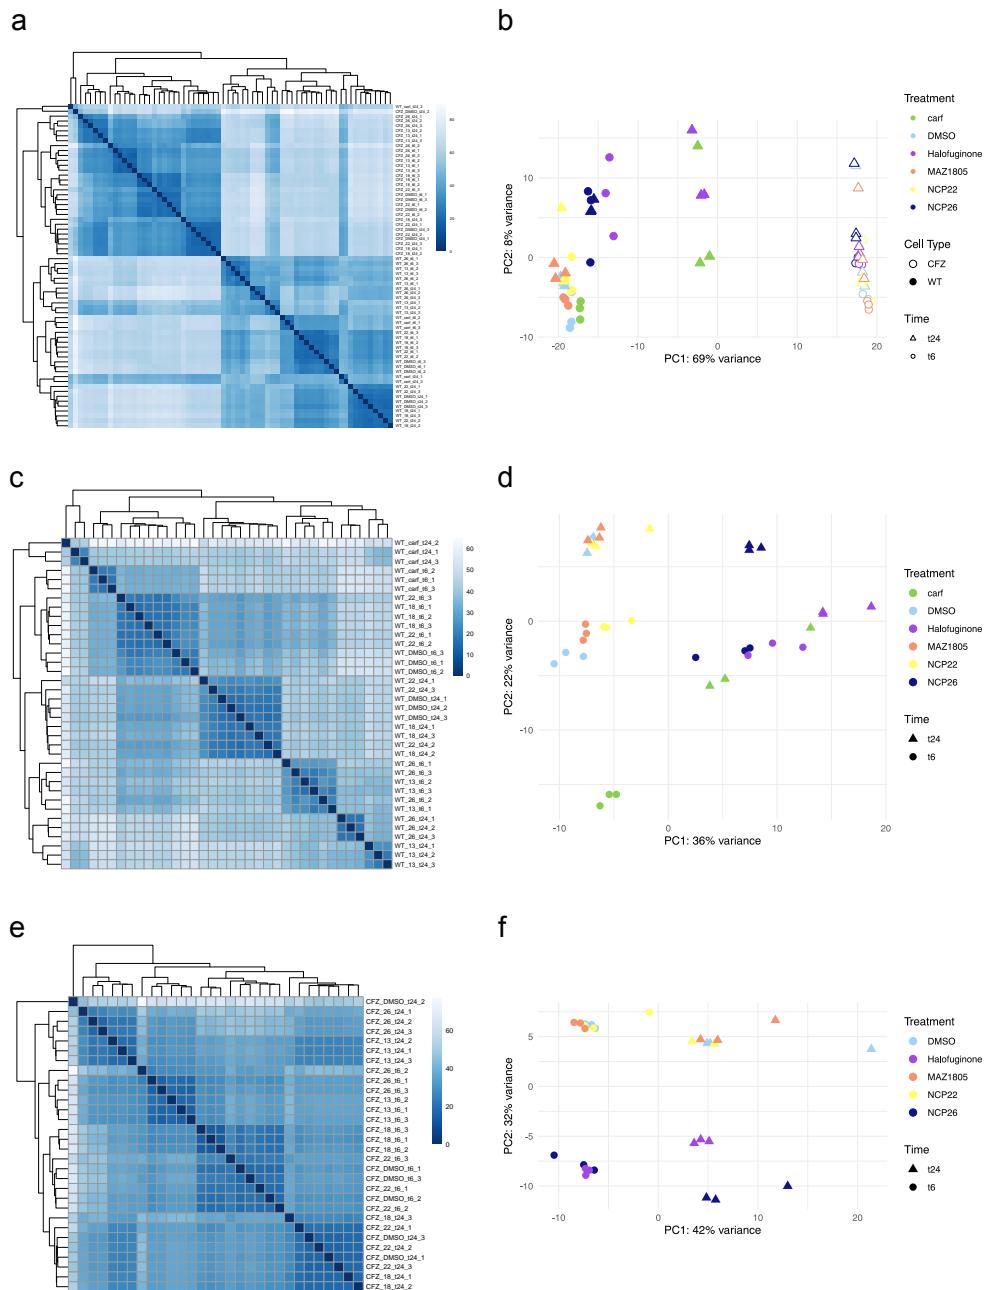

Figure 5.5: Bulk RNA-seq sample clustering. WT AMO-1 cells and CFZr L363 cells treated for 6 or 24 hours with a DMSO control, 100nM carfilzomib or 1uM of a ProRS inhibitor (MAZ1392/halofuginone, MAZ1805/halofuginol, NCP26 and NCP22). Clustering analysis of sample-sample distances (a, c and e) and principal component analysis (PCA; b, d and f). a) and b) both cell types (WT and CFZr) displayed; c) and d) WT AMO-1 only; e) and f) CFZr samples only.

to the ProRS inhibitors, but culminating in a similar response as time progresses, such as cell stress and cell death pathways.

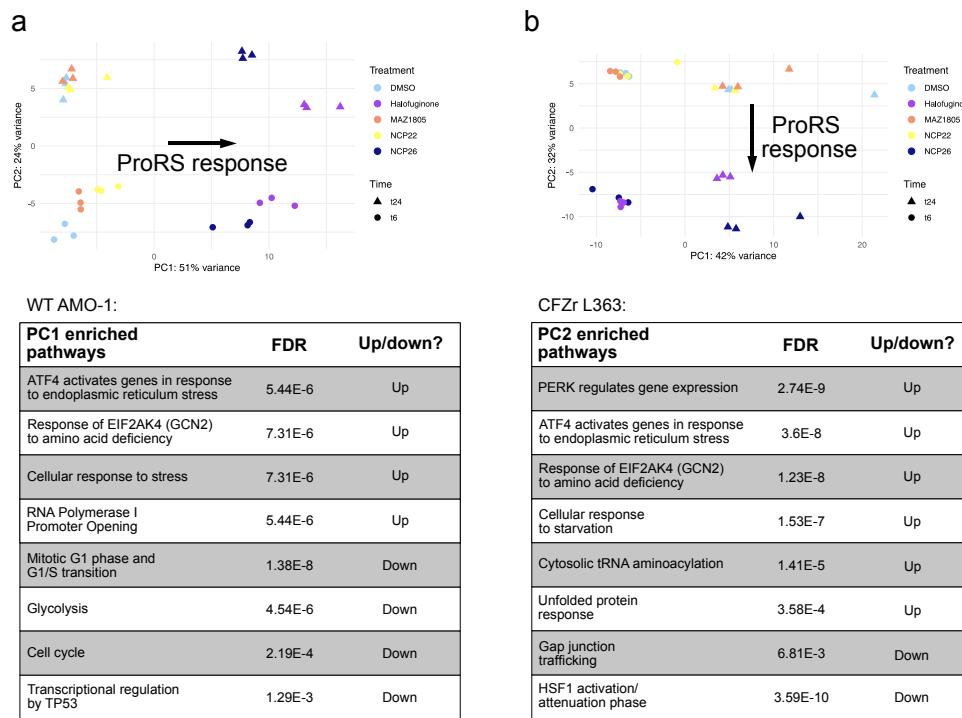

Figure 5.6: principal component analysis (PCA) pathway enrichment. Pathway enrichment analysis performed using REACTOME of top contributing genes from PCA. a) WT AMO-1 dataset with carfilzomib-treated samples removed. PC1 seems to account for the separation between DMSO controls/ less active compounds and the more active ProRS inhibitors (NCP26 and halofuginone). Genes contributing positively towards PC1 are upregulated in NCP26 and halofuginone compared to DMSO controls and less active compounds. Enriched pathways from top genes in PC1 shown beneath PCA plot. b) CFZr L363 dataset. PC2 seems to account for the separation between DMSO controls/ less active compounds and the more active ProRS inhibitors (NCP26 and halofuginone). Genes contributing negatively towards PC2 (down arrow), are upregulated in NCP26/ halofuginone compared to controls. Pathways enriched from top genes in PC2 shown beneath PCA plot.

The top principal components of the WT AMO-1 and CFZr datasets were examined more closely. Carfilzomib-treated samples were removed from the WT dataset, to ensure that the difference between controls and active ProRS inhibitors was captured in PC1 or PC2 following dimensionality reduction. Differential expression, variance stabilising transformation and PCA was re-performed to the CFZ-less dataset. Pathway enrichment analysis was performed for the top genes

from the principal component accounting for the difference between controls and halofuginone/NCP26 treatment (PC1 for WT cells, PC2 for CFZr cells; Figure 5.6). The pathways ‘ATF4 activates genes in response to ER stress’, ‘Response of GCN2 to amino acid deficiency’ and ‘cytosolic tRNA aminoacylation’ were all enriched, suggesting that the amino acid response is activated. The ‘unfolded protein response’ (UPR) was also enriched, as well as ‘PERK regulates gene expression’. The UPR is a member of the integrated stress response (ISR), so many genes involved in the UPR overlap with genes involved in the AAR. *PERK* regulates the translation response of the UPR. Additionally, genes involved in the cell cycle and G1/S transition are negatively enriched. Previously, HF has been shown to induce the accumulation of cells in the G₀/G₁ cell cycle[115].

5.3.3 Drug sensitive MM cells

For AMO-1 WT cells at 6 hours, 2119 genes were differentially expressed ($|\log_2 FC| > 0.5$ and $p_{adj} < 0.05$; DE) for NCP26 treated-samples, 3019 DE genes (DEGs) for halofuginone, 33 DEGs for MAZ1805, 218 DEGs for NCP22, and 983 DEGs for carfilzomib-treated samples compared to DMSO controls. At 24 hours, 3323 DEGs for NCP26-treated samples, 3426 DEGs for halofuginone, 2 DEGs for MAZ1805 and 2260 DEGs for carfilzomib treated samples compared to DMSO controls. DEGs for NCP26 and halofuginone treatment are shown in Figure 5.7. Genes highly differentially expressed by the ProRS inhibitors are coloured and annotated with their gene symbol. Numerous genes involved in stress response pathways can be seen to be upregulated following NCP26 and halofuginone treatment, including *TRIB3*, *JUN* and *ATF3*. Additionally, various histone genes are upregulated. Some genes involved in cell cycle progression, such as *CDKN1A*, are downregulated following ProRS inhibition. Interestingly, *PYCR1* (a gene which encodes for an enzyme in the final step of the conversion of glutamine into proline) was found to be upregulated following NCP26 and HF treatment at 6 and 24 hours. This could be an attempt by the MM cells to make more proline to overcome the apparent ‘proline-deficiency’.

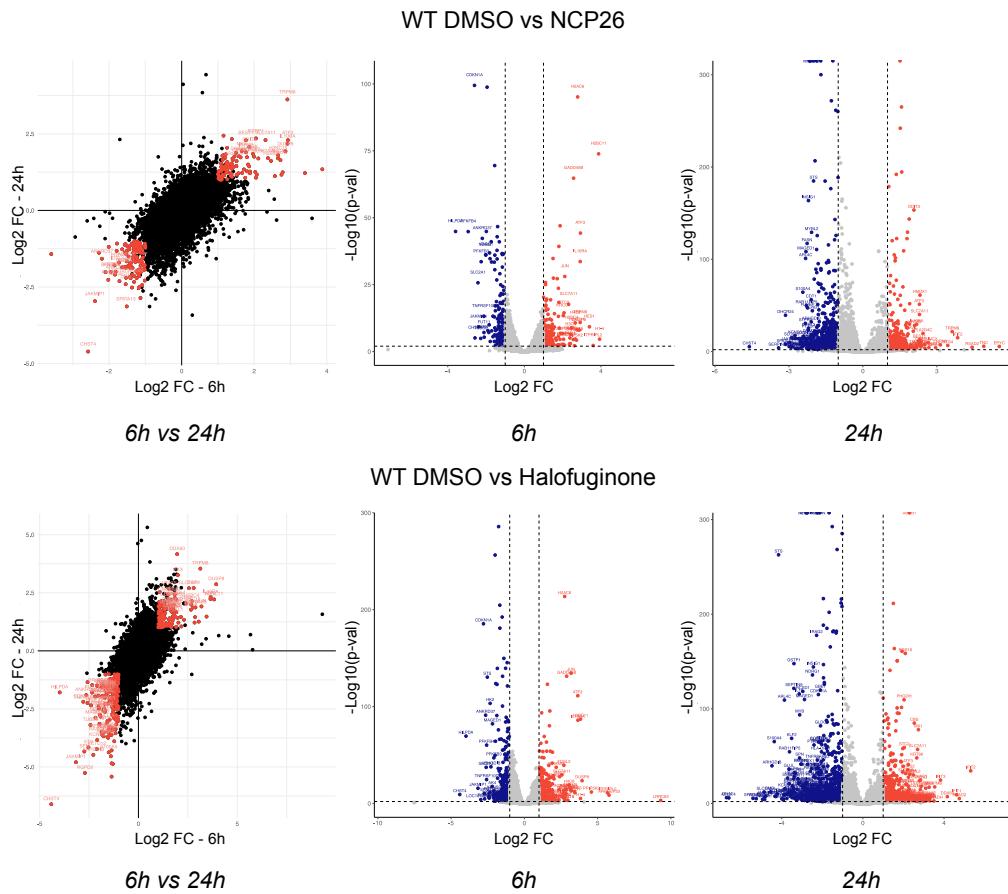

Figure 5.7: Differentially expressed genes (DEGs) for halofuginone and NCP26 treated WT AMO-1 cells at 6 and 24 hours. Scatter plot of genes for 6 hours treated vs 24 hours treated. Red points indicate genes which are differentially expressed ($p_{adj} < 0.01$) at both 6 and 24 hours. Volcano plots are also shown. Blue points indicate downregulated DEGs ($p_{adj} < 0.01$ & $\log_2 FC < -1$). Red points indicate upregulated DEGs ($p_{adj} < 0.01$ & $\log_2 FC > 1$). Top DEGs are annotated with HGNC symbols.

Transcriptional changes for 6 hours of exposure to NCP26 were compared with proteomic changes for the same treatment condition (Figure 5.8). Proteomic data was supplied by collaborators: Keiji Kurata, Teru Hidemitsu and Ken C Anderson (Dana-Farber Cancer Institute; DFCI).

Consistent with a mechanism of a global reduction of protein synthesis (with the exception of preferential translation of *ATF4*) upon ISR induction and eIF2 α phosphorylation, very few proteins with an increased abundance were identified (52 proteins with a \log_2 fold-change between 0.2 and 0.64). Additionally, a larger shift of proteins with lower abundance in NCP26 samples compared to DMSO was found. This correlates with transcriptional data where more DEGs were downregulated

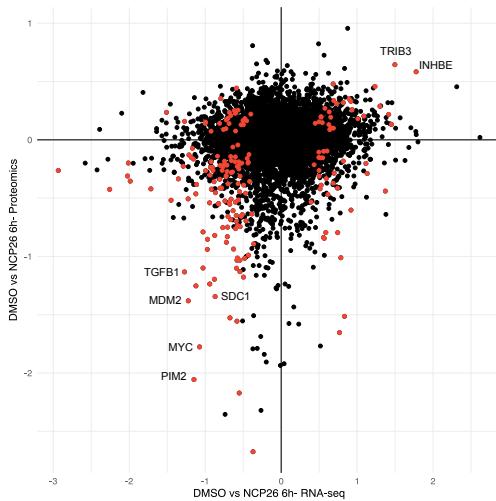

Figure 5.8: Scatterplot of proteomic and RNA-seq datasets depicting changes after 6hr NCP26 exposure to AMO-1 cells. Red points indicate genes which are differentially expressed ($p_{adj} < 0.01$) in both RNA-seq and proteomic datasets. Following NCP26 treatment, TRIB3 and INHBE (both *ATF4* targets) were the proteins with the highest increase in abundance ($\log_2 FC = 0.64$ and $\log_2 FC = 0.58$) in the proteomic dataset and both were significantly upregulated in the RNA-seq dataset. I analysed proteomic data supplied by Keiji Kurata, Teru Hideshima and Ken C Anderson (Dana-Farber Cancer Institute; DFCI).

than upregulated for all ProRS inhibitor treatment conditions. Also, in-fitting with this mechanism, selective *ATF4* target genes are upregulated, such as *TRIB3* and *INHBE* (as seen highlighted in Figure 5.8). This shows a dominant role of the integrated stress response at 6 hours on the transcriptomic and proteomic level.

The effects of NCP26 and halofuginone treatment on the amino acid starvation response were examined in more detail. AAR genesets ‘GOBP response to amino acid starvation’, ‘REACTOME response of EIF2AK4/GCN2 to amino acid deficiency’ and ‘KRIGE amino acid deprivation’ were collated from the Molecular Signatures Database (MSigDb), making up a list of 166 unique genes.

This list of AAR genes was intersected with DEGs for ProRS inhibitor-treatment (i.e NCP26 vs DMSO and halofuginone vs DMSO at 6 or 24 hours) and a heatmap was constructed (Figure 5.9). The AAR transcription factors *ATF3*, *DDIT3* (CHOP), *CEBPB* and *CEBPG* are all markedly upregulated following NCP26 and halofuginone treatment. Amino acid transporters, such as *SLC7A11*, were also upregulated

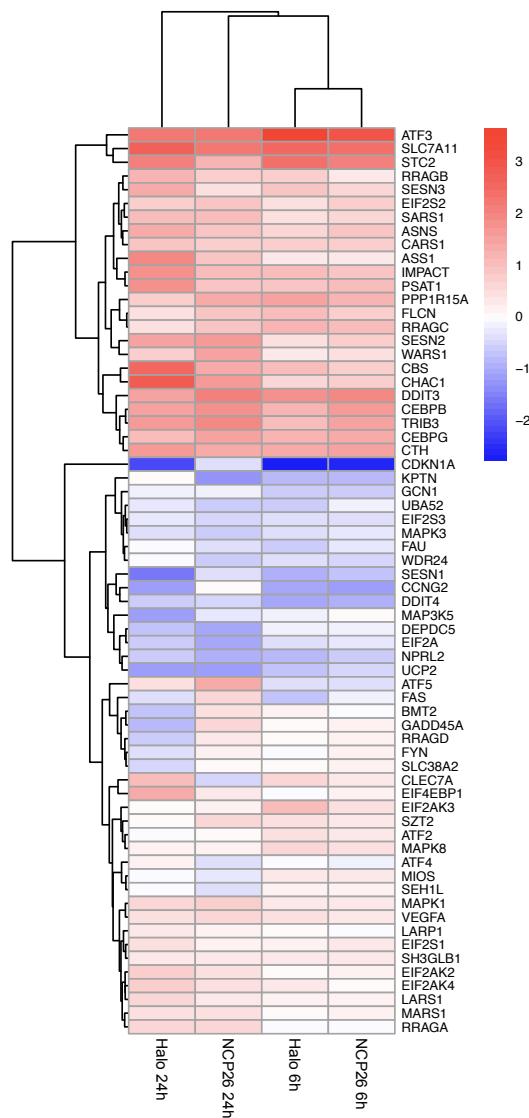

Figure 5.9: Heatmap of amino acid starvation response (AAR) genes for WT cells treated with NCP26 and halofuginone. Differentially expressed genes (DEGs) that are involved in the AAR. A list of known AAR genes was compiled by collating AAR genesets from the Molecular Signatures Database (MSigDb). The colour scale shows log₂ fold change of expression for each treated sample, compared to its DMSO time control. Red indicates an upregulated gene and blue indicates a downregulated gene.

following ProRS inhibitor treatment. Genes coding for aminoacyl tRNA synthetases were also seen to be upregulated, such as *WARS1*, *SARS1* and *CARS1*. In total,

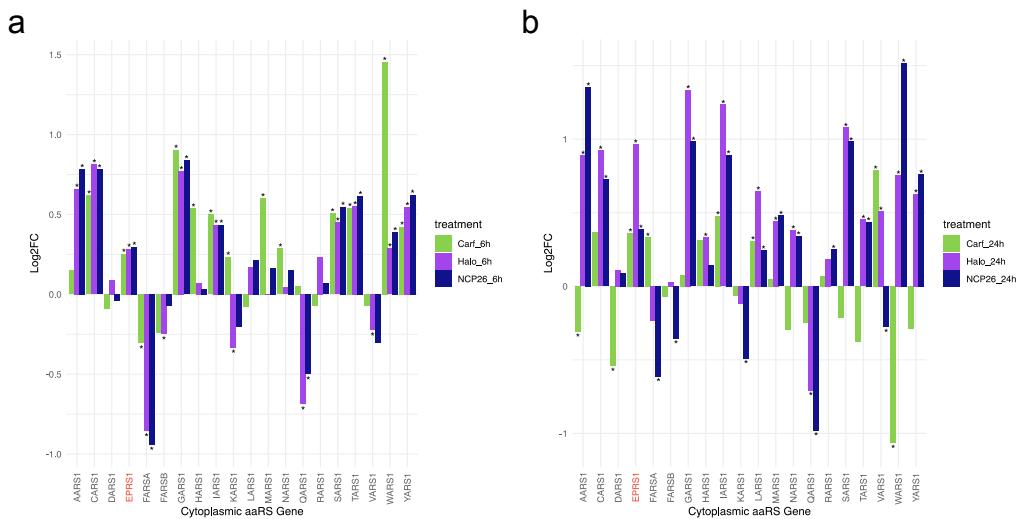

Figure 5.10: Cytoplasmic aaRS gene expression change. \log_2 fold change for ProRS inhibitor/carfilzomib treated samples compared to DMSO controls. Stars indicate significance at adjusted p-value < 0.05. *EPRTS1* (the target of NCP26 and halofuginone) is highlighted in red.

nine cytoplasmic aaRS genes were overexpressed ($p_{adj} < 0.05$) after 6 hours of ProRS inhibition, and 14 cytoplasmic aaRS genes were overexpressed after 24 hours (Figure 5.10). *EPRTS1* was upregulated following NCP26 and halofuginone treatment, at 6 and 24 hours. *QARS1*, *KARS1* and *FARSA* (coding for the alpha subunit of *FARS1*) were found to be the most downregulated cytoplasmic aaRS genes, following ProRS inhibition. Mitochondrial aaRS gene expression changes are shown in Figure A.1.

A list of 287 unique genes activated by *ATF4* was compiled from the genesets: ‘REACTOME ATF4 activates genes in response to endoplasmic reticulum stress’ and ‘ATF4 Q2’ (genes having at least one occurrence of the transcription factor binding site V.ATF4 Q2 in the regions spanning up to 4 kb around their transcription starting sites). Figure 5.11 shows a heatmap for DE *ATF4* activated genes. Numerous *ATF4* targets can be seen to be differentially expressed following ProRS inhibition with NCP26 and HF. Of the 287 genes in the list, 165 genes were DE with NCP26 or HF treatment.

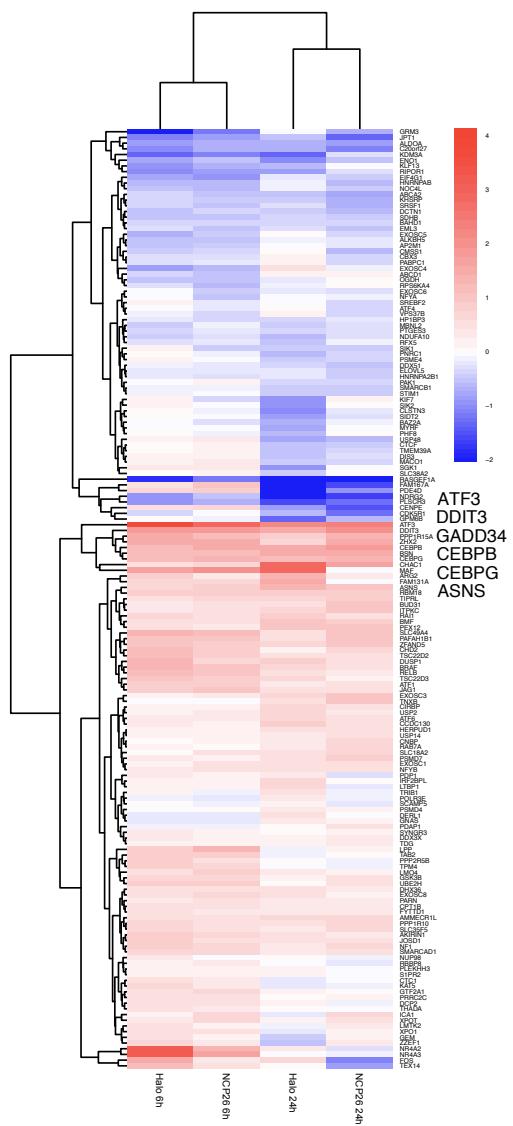

Figure 5.11: Heatmap of *ATF4* activated genes for WT cells treated with NCP26 and halofuginone. Differentially expressed genes (DEGs) *ATF4* activated genes. A list of genes activated by the transcription factor *ATF4* was compiled by collating genesets from the Molecular Signatures Database (MSigDb). The colour scale shows \log_2 fold change of expression for each treated sample, compared to its DMSO time control. Red indicates an upregulated gene and blue a downregulated gene.

Taken together, it is clear that following HF and NCP26 treatment of AMO-1 MM cells, the amino acid starvation response is activated, mediated via the transcription factor *ATF4* and culminating in ER stress and downstream apoptotic mechanisms.

ProRS inhibitors vs carfilzomib

Since their first use in MM 30 years ago, the mechanism of action of proteome inhibitors has been extensively studied and well described by researchers (such as [261]). Figure 5.5d demonstrates similarities at 24 hours between the transcriptional effects of ProRS inhibitors and the proteasome inhibitor carfilzomib on AMO-1 cells. It also demonstrates ProRS and carfilzomib-treated samples separation at 6 hours, highlighting differences in their initial mechanism of action.

The similarities and differences between ProRS inhibitors and carfilzomib were studied in more detail. As seen by x-y trends of scatter plots and number of overlapping genes in Venn diagrams (Figure 5.12a and b), ProRS inhibitors and carfilzomib treatment are more similar at 24 hours, and share more DEGs (compared to DMSO controls), than at 6 hours. Somewhat obviously, NCP26 and HF share more overlapping DEGs with each other than with CFZ. HF shares more overlapping DEGs with CFZ than NCP26. This is likely to do with potency and dosing, where both HF and CFZ were used at approximately 10 times their IC₅₀ value.

Carfilzomib treatment of AMO-1 cells resulted in a pronounced induction of the heat shock response, changes to ubiquitin mediated processes and protein folding, in line with the well-defined cellular changes of proteasome inhibition. At 6 hours, some ISR effectors, such as *ATF3* and *JUN*, were upregulated by both carfilzomib and NCP26/halofuginone treatment.

At 24 hours, CFZ and ProRS inhibitor treatment seem to culminate in similar end-stage stress, cell cycle changes and apoptotic mechanisms. Both ProRS inhibition and CFZ treatment resulted in pathway enrichment of ‘cell cycle arrest’, ‘negative regulation of cell proliferation’, ‘positive regulation of apoptosis process’ and ‘type 1 interferon signalling pathway’. Figure 5.12d shows a heatmap of NCP26, HF and CFZ for log₂FC compared to DMSO controls at 6 and 24 hours for selected genes,

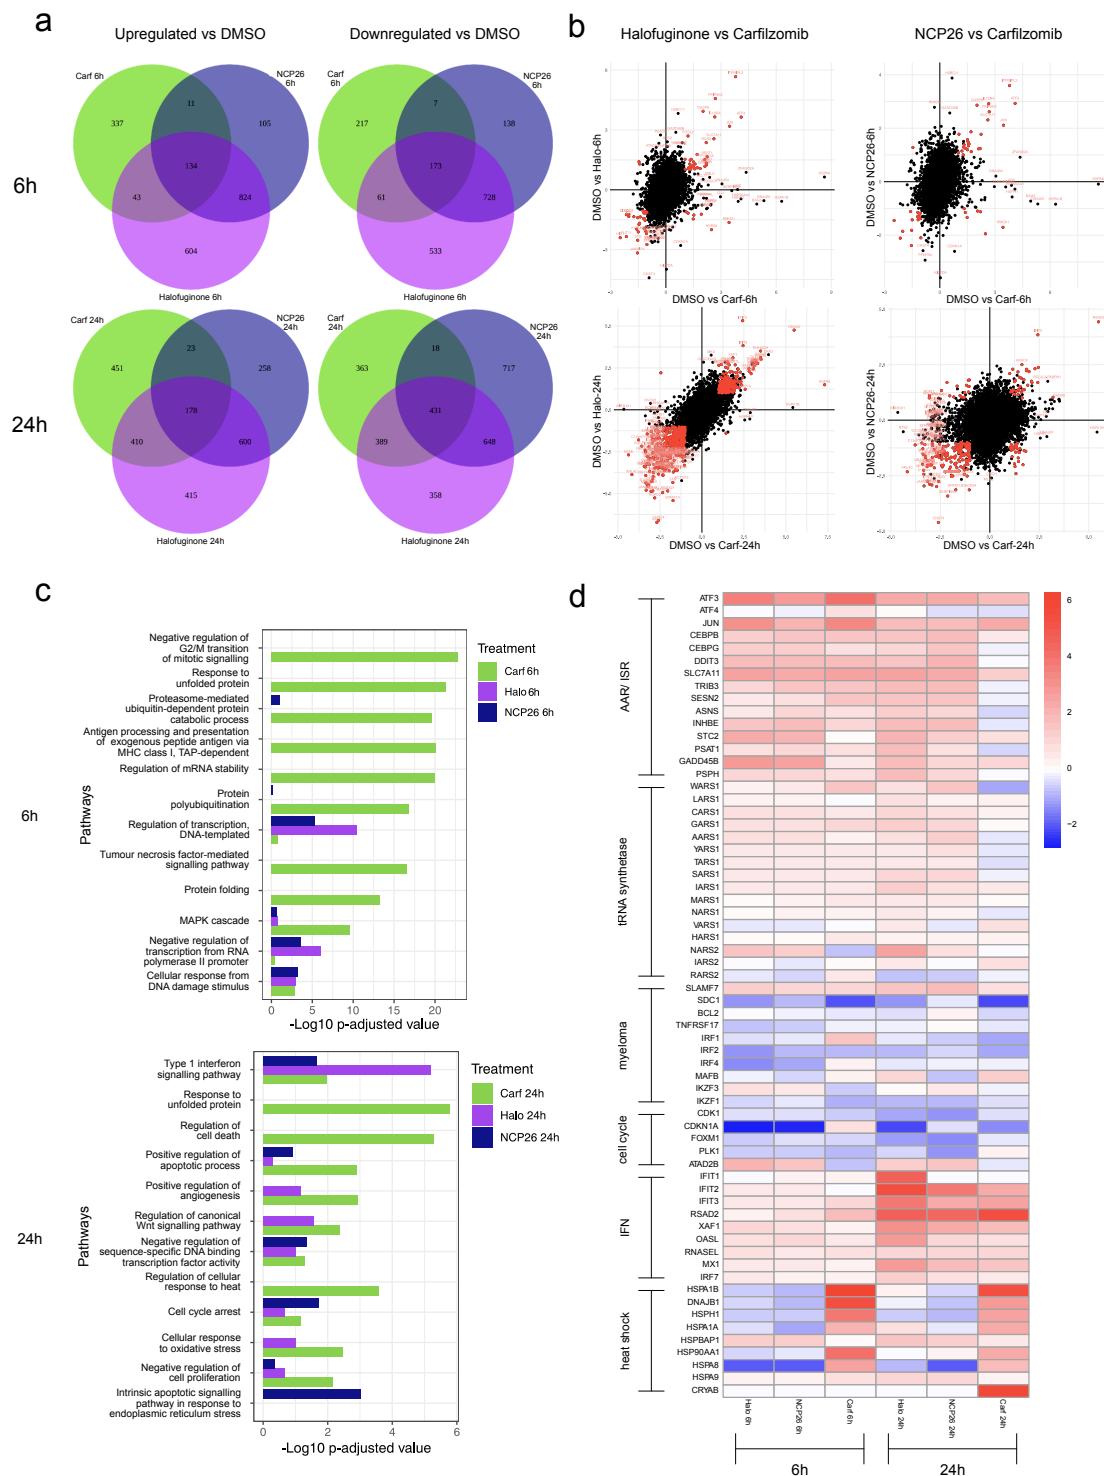

Figure 5.12: ProRS inhibitors compared with carfilzomib's mechanism of action. a) Venn diagrams showing overlapping differentially expressed genes (DEGs; upregulated or downregulated following treatment) at 6 and 24 hours. b) Scatter plots showing correlation of carfilzomib DEGs against halofuginone or NCP26 DEGs. c) Pathway analysis (Gene ontology biological processes; GOBP) for top upregulated genes. d) Heatmap of selected differentially expressed genes upon carfilzomib, halofuginone and NCP26 treatment.

belonging to various pathways/ classes. NCP26 and HF demonstrated similar effects on MM markers as CFZ, such as downregulating the MM pathological marker *SDC1/ CD138*. CFZ is an established anti-MM therapy approved in the clinic, therefore this is a promising sign for the effectiveness of ProRS inhibitors in MM.

5.3.4 Carfilzomib-resistant MM cells

For CFZr L363 cells at 6 hours, 1165 genes were DE for NCP26 treated-samples, 2424 DEGs for HF, 222 DEGs for MAZ1805, and 0 DE genes for NCP22-treated samples compared to DMSO control samples. At 24 hours, 852 DEGs for NCP26-treated samples, 256 DEGs for HF, no genes were DE for MAZ1805 and NCP22 compared to DMSO controls. DEGs for NCP26 and HF treatment are shown in Figure 5.13. Numerous genes involved in the AAR can be seen to be upregulated following NCP26 and halofuginone treatment, including *TRIB3*, *ATF3*, *CHAC1*, *INHBE*, *PSAT1*, *ASNS* and *SESN2*; Amino acid transporters *SLC7A11* and *SLC6A9*, and tRNA aminoacyl synthetase *WARS1* are also upregulated.

Pathway enrichment analysis

Pathway enrichment analysis was performed for the top DE genes for NCP26 and HF treated samples compared to DMSO controls (Figure 5.14). Multiple pathways relating to endoplasmic reticulum stress and apoptosis were enriched following ProRS inhibition. ‘Cellular response to amino acid starvation’ was enriched, along with ‘amino acid transport’, indicating that NCP26 and HF likely activate the amino acid starvation response in the CFZ resistant MM cells. Additionally the pathway ‘response to unfolded protein’ was enriched. The unfolded protein response is part of the integrated stress response so shares many of the same effectors as the AAR, such as *DDIT3* (CHOP).

The amino acid response was investigated more closely for the PI-resistant cell line. Figure 5.15 shows a heatmap of DEGs for NCP26/HF treated CFZr cells at 6 or 24 hours, which are known members of the AAR (collated from MSigDbl– as above).

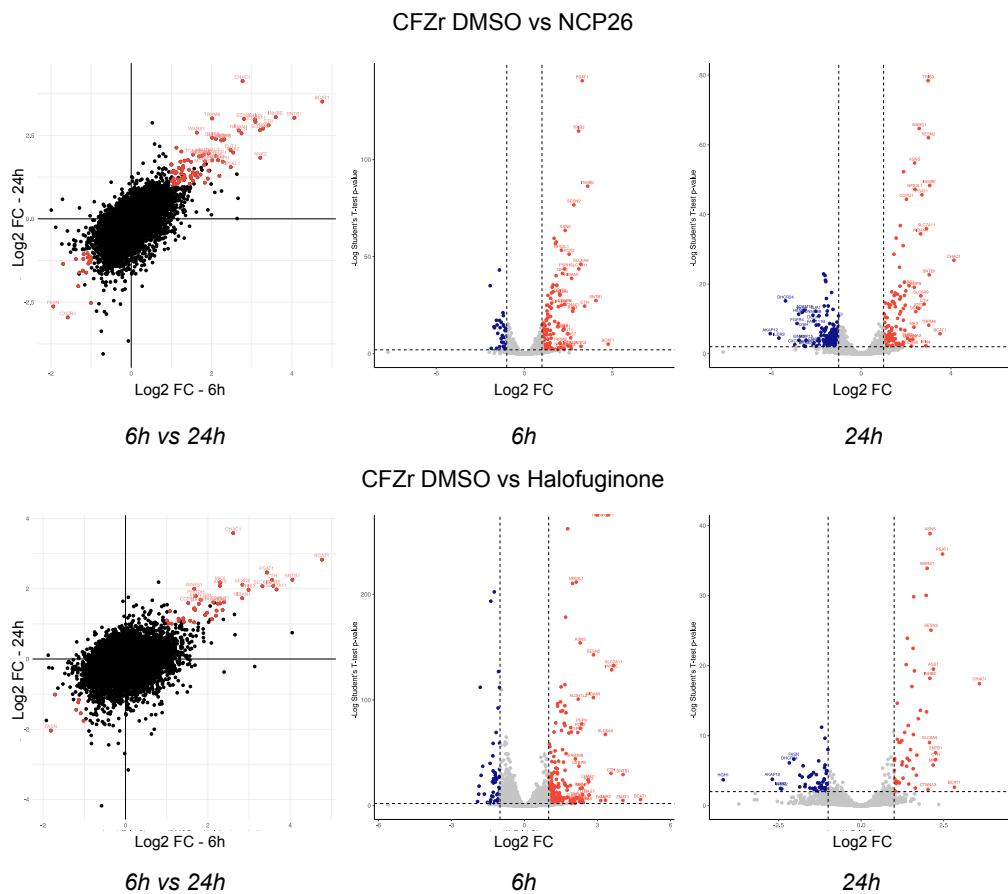

Figure 5.13: Differentially expressed genes (DEGs) for HF and NCP26 treated CFZr L363 cells at 6 and 24 hours. Scatter plot of genes for 6 hours treated vs 24 hours treated. Red points indicate genes which are differentially expressed ($p_{adj} < 0.01$) at both 6 and 24 hours. Volcano plots are also shown. Blue points indicate downregulated DEGs ($p_{adj} < 0.01$ & $\log_2 FC < -1$). Red points indicate upregulated DEGs ($p_{adj} < 0.01$ & $\log_2 FC > 1$). Top DEGs are annotated with HGNC symbols.

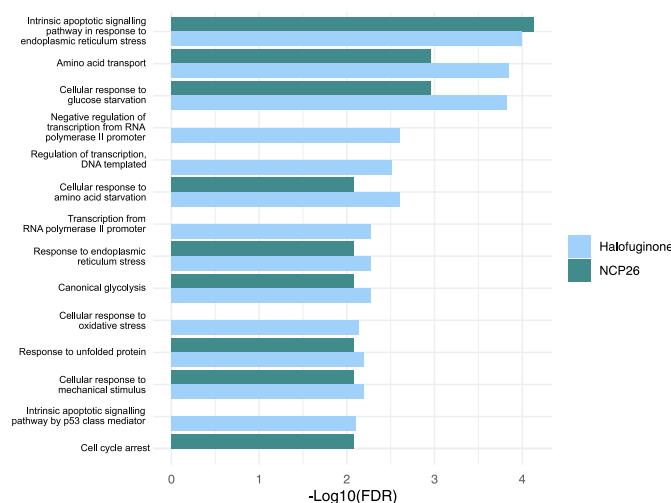

Figure 5.14: Pathway analysis (Gene ontology biological processes; GOBP) performed for top DE genes at 24 hours.

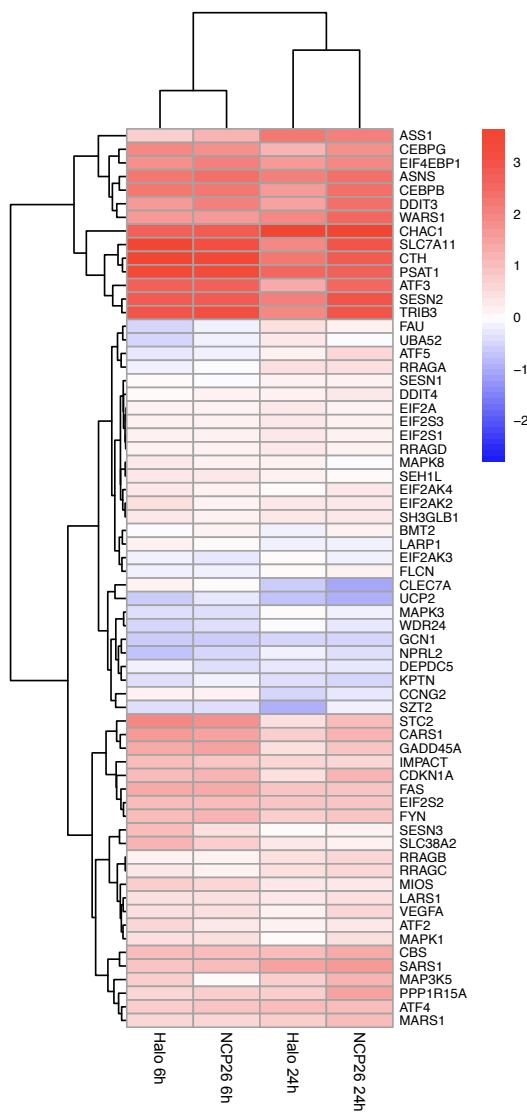

Figure 5.15: Heatmap of amino acid starvation response (AAR) for CFZr cells treated with ProRS NCP26 and halofuginone. Differentially expressed genes (DEGs) that are involved in the AAR. A list of known AAR genes was compiled by collating AAR genesets from the Molecular Signatures Database (MSigDb). The scale denotes log 2 fold change vs each sample's corresponding control. Red indicates upregulated genes and blue indicates downregulated genes.

A strong response of the AAR can be seen following NCP26 and HF treatment. The transcription factors *CEBPG*, *CEBPB*, *ATF3*, *DDIT3* are strongly upregulated, along with amino acid transporter *SLC7A11*. Other AAR genes are strongly upregulated with ProRS inhibitor treatment, such as *ASS1*, *ASNS*, *CHAC1*, *PSAT1*, *PPP1R15A/GADD34* and *TRIB3*.

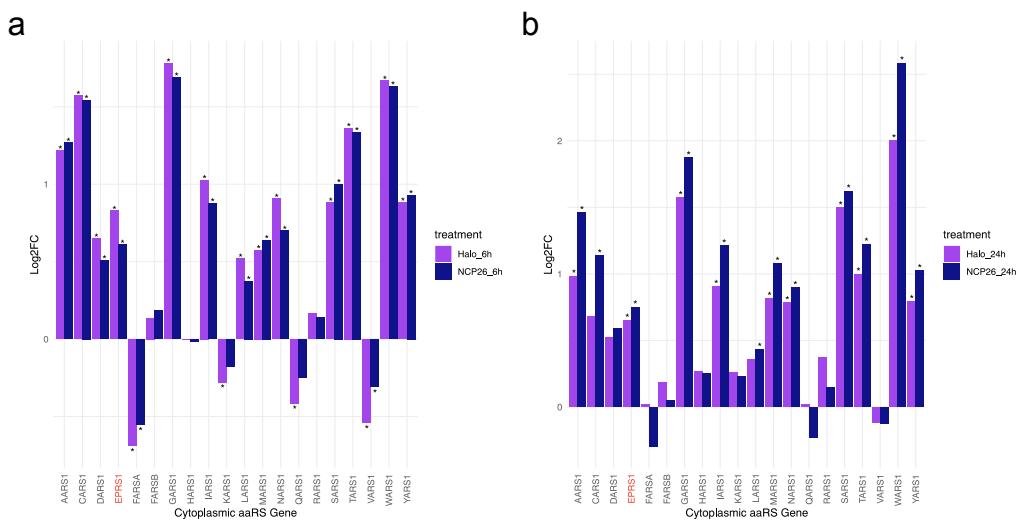

Figure 5.16: Cytoplasmic aaRS gene expression change CFZr cells. Log2 fold change for ProRS inhibitor/carfilzomib treated samples compared to DMSO controls. Stars indicate significance at adjusted p-value < 0.05 . *EPERS1* (the target of NCP26 and halofuginone) is highlighted in red.

In total, 13 cytoplasmic aaRS genes were overexpressed ($p_{adj} < 0.05$) after 6 hours of ProRS inhibition, and 12 cytoplasmic aaRS genes were overexpressed after 24 hours in CFZr cells (Figure 5.16). Like in WT cells, *EPERS1* was upregulated following NCP26 and HF treatment, at 6 and 24 hours. *WARS1* and *GARS1* were strongly overexpressed following ProRS inhibition. Similar to treatment of WT AMO-1 cells, *QARS1*, *KARS1*, *FARSA* and *VARS1* did not follow the trend and gene expression of these genes was found to be downregulated in ProRS inhibitor treated samples. Perhaps this indicates a tumour suppressive role of these aminoacyl-tRNA synthetases.

Figure 5.17 shows a heatmap for ATF4 activated genes (as above) and genes DE by NCP26 and HF in CFZr cells. Numerous *ATF4* targets can be seen to be differentially expressed following ProRS inhibition with NCP26 and HF. Of the 287

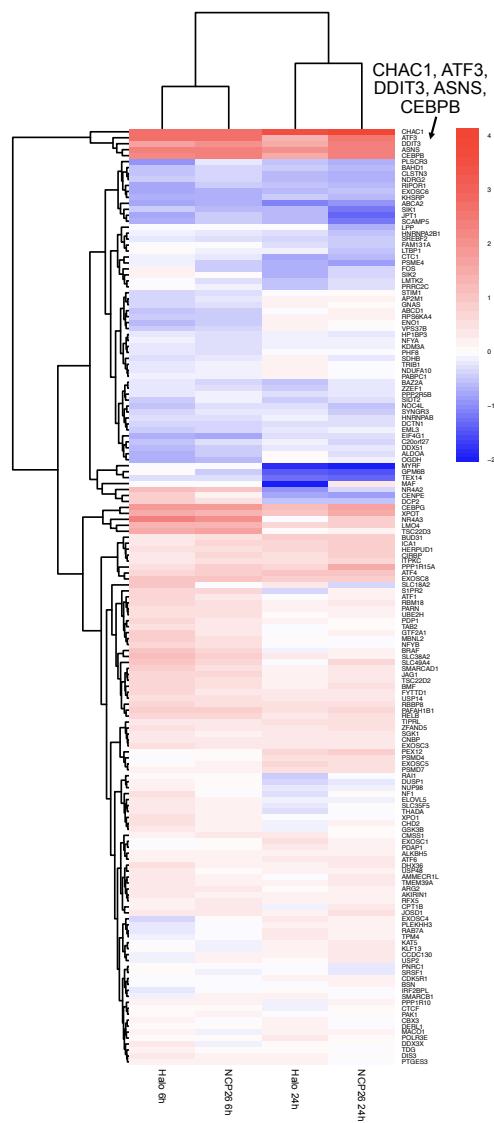

Figure 5.17: Heatmap of *ATF4* activated genes for CFZr L363 cells treated with NCP26 and halofuginone. *ATF4* activated genes, which are differentially expressed following NCP26 or halofuginone treatment at 6 or 24 hours. A list of genes activated by the transcription factor *ATF4* was compiled by collating genesets from the Molecular Signatures Database (MSigDb). The colour scale shows \log_2 fold change of expression for each treated sample, compared to the corresponding DMSO control. Red indicates an upregulated gene and blue a downregulated gene.

genes activated by *ATF4* in the list, 157 genes were differentially expressed with NCP26 or HF treatment. This indicates that many *ATF4* downstream targets are being mediated, indicating that *ATF4* has high transcriptional activity.

CFZ-resistant L363 cells show a similar engagement of the AAR and activation of *ATF4*-mediated genes as PI-sensitive AMO-1 cells, following NCP26/HF treatment. Additionally many downstream apoptotic mechanisms are enriched, indicating the initiation of cell death by AAR activation. Taken with the cytotoxicity dose response data, this demonstrates that ProRS inhibitors are capable of killing PI-resistant MM cell lines. Thus targeting the ProRS could be a potential effective strategy in overcoming PI drug resistance in clinical MM.

5.4 ProRS inhibitor resistance bulk RNA-seq

5.4.1 Experiment overview

Bulk RNA-seq was performed to explore the transcriptional changes of MM cells which had become resistant to ProRS inhibition. Dr James Dunford created a NCP26 resistant cell line (NCP26R) by continually exposing L363 cells to NCP26, and gradually increasing NCP26 concentration over time. NCP26R cells at time of sequencing were growing in 1 μ M NCP26, with an IC₅₀ of approximately 1.6 μ M. Normal L363 cells have an IC₅₀ of approximately 0.5 μ M for NCP26. Triplicates of normal L363 cells and NCP26R L363 cells were harvested and prepared for sequencing as in Section 3.4.

5.4.2 Results

As expected, the samples clustered into two distinct groups: control L363 samples and NCP26R samples (Figure A.5a and b). The differences between the two cell groups made up most of the variance in the dataset (PC1 = 90% overall variance).

4129 genes were differentially expressed ($|log_2FC| > 0.5$ and $p_{adj} < 0.05$; DE) between NCP26R L363 samples and L363 controls (Figure 5.18a). The log₂FC for cytoplasmic aaRS genes is shown in Figure 5.18b. Nine out of 20 aaRS genes were upregulated ($p_{adj} < 0.05$) in NCP26-resistant cells, including *EPRS1*. Four aaRS

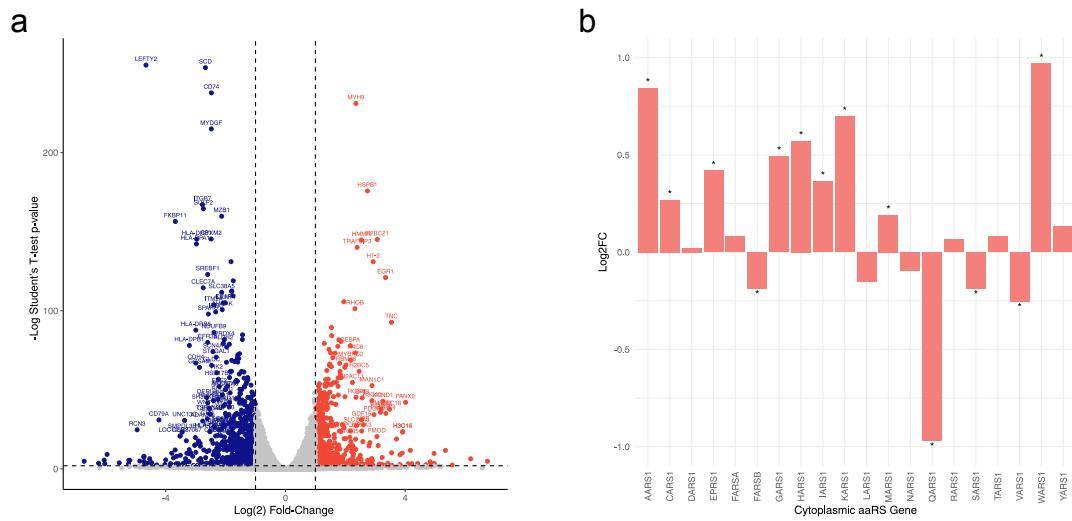

Figure 5.18: Differentially expressed genes (DEGs) for NCP26R L363 cells vs L363 controls. a) Volcano plot. Blue points indicate downregulated DEGs ($p_{adj} < 0.01$ & $\log_2 FC < -1$). Red points indicate upregulated DEGs ($p_{adj} < 0.01$ & $\log_2 FC > 1$). Top DEGs are annotated with HGNC symbols. b) $\log_2 FC$ of cytoplasmic aaRS genes. Stars indicate differential expression ($p_{adj} < 0.05$). *EPRS1* is upregulated in NCP26R cells.

genes were downregulated ($p_{adj} < 0.05$), including *QARS1* and *VARS1*, which were also downregulated following ProRS inhibitor treatment. *PYCR1*, *PYCR2* and *PYCR3* (genes which encode for the three enzymes in the final step of the conversion of glutamine into proline) were found to be downregulated in NCP26R cells.

Next, pathway enrichment analysis was performed using the packages ClusterProfiler and XGR with gene ontology (GO) annotations. Chromatin remodelling and assembly, DNA packaging, and nucleosome organization and assembly pathways were enriched in NCP26R cells. Numerous histone genes were upregulated in NCP26R cells. ER-associated pathways were found to be suppressed in NCP26R cells, including ‘integral component of luminal side of endoplasmic reticulum membrane’, ‘ER to Golgi transport vesicle membrane’, ‘endoplasmic reticulum lumen’. This may indicate transcriptional changes are made to ER-associated genes to overcome and become more resistant to ER stress produced by ProRS inhibition. Antigen binding and MHC class II protein complex pathways were also suppressed in NCP26R cells, as well as components of the ECM and plasma membrane. Some members of the UPR and ISR were enriched in NCP26R cells.

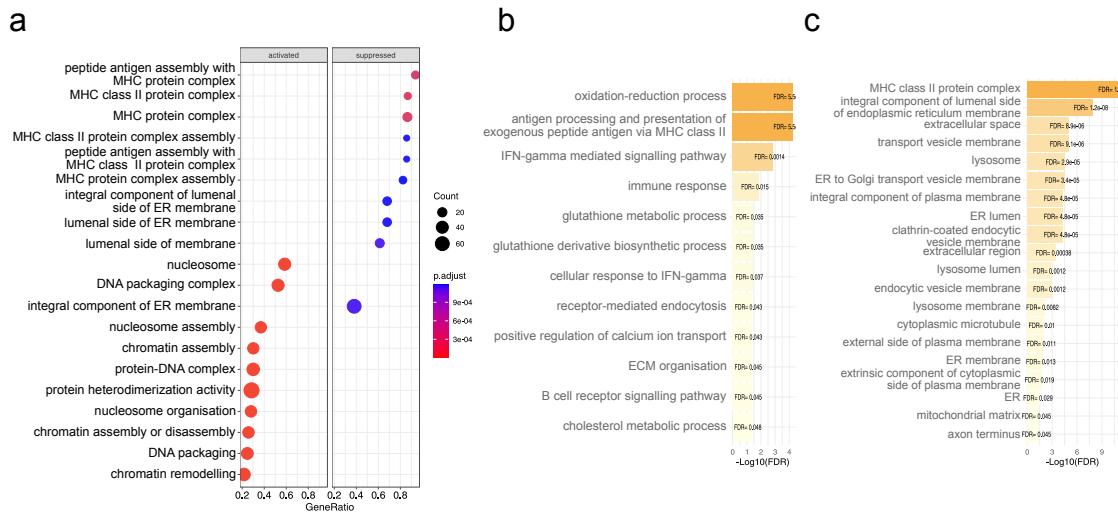

Figure 5.19: Pathway enrichment analysis for NCP26R L363 cells vs L363 controls. a) Gene set enrichment analysis (GSEA) using biological processes (BP), molecular function (MF), and cellular compartment (CC) gene ontology (GO) annotations. Genes ordered by $\log_2 FC$ values. b) XGR GOBP enrichment analysis for top downregulated DEGs ($p_{adj} < 0.05$ & $\log_2 FC < -1$). c) XGR GOCC enrichment analysis for top downregulated DEGs ($p_{adj} < 0.05$ & $\log_2 FC < -1$).

NCP26R cells had a number of DEGs that relate to ER structure and function. Given the known involvement of ER stress and the ISR in NCP26's mechanism of action, transcriptional changes to the amino acid starvation response were explored. 47 AAR genes were differentially expressed ($p_{adj} < 0.05$) in NCP26R cells compared to controls (Figure 5.20). Many of the AAR genes seem to follow similar expression changes as with NCP26 treatment, such that many AAR genes that were upregulated (downregulated) following NCP26 treatment, were also upregulated (downregulated) in NCP26R cells. For example, transcription factors *ATF3*, *DDIT3*, *CEPB* and *CEPBG* are all overexpressed in NCP26R cells vs controls, and NCP26-treated cells vs DMSO-treated cells. However, some AAR genes did not follow this pattern. The master amino acid regulator, *ATF4*, was downregulated in NCP26R cells, yet is upregulated following ProRS inhibitor treatment in CFZr cells. Previously, it has been shown that *ATF4* knockdown (but not *ATF3*) has rendered tumour cells resistant to amino acid starvation[262]. *CHAC1* was also downregulated in NCP26R cells. Overexpression of *CHAC1* has been implicated in ER stress, oxidative stress and apoptosis[263]. *EIF2A* (coding for eIF2 α) is also

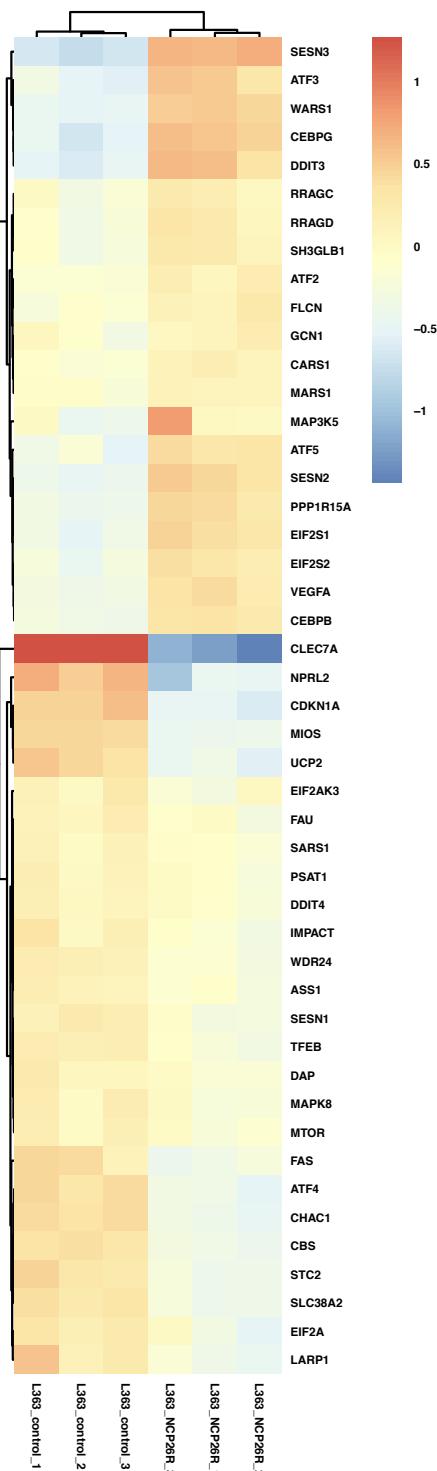

Figure 5.20: Heatmap of amino acid starvation response (AAR) genes for NCP26R cells. Differentially expressed genes (DEGs) involved in the AAR. A list of known AAR genes was compiled by collating AAR genesets from the Molecular Signatures Database (MSigDb). Normalised gene counts are shown for each sample.

downregulated in NCP26R cells. Phosphorylation of eIF2 α by GCN2 or PERK (sensors of AAR and UPR, respectively) results in *ATF4* activation. *FAS*, which encodes TNF receptor superfamily member 6, a receptor involved in the induction of apoptosis, was downregulated in NCP26R cells. Moreover *CDKN1A* and *MIOS* were downregulated in NCP26R cells compared to controls, yet are upregulated following ProRS inhibition in CFZr cells. As mentioned, a well-known function of *CDKN1A* is to arrest cell cycle progression, it is also thought to be instrumental in the execution of apoptosis following caspase activation.

These transcriptional changes in NCP26R cells, indicate that greater ProRS inhibition is required in this cell line to overcome reduced *EIF2A*, *CHAC1* and *ATF4* expression and to tip the balance of ER stress from pro-survival to pro-death signalling. These adaptations further corroborate the involvement of the AAR in the mechanism of action and effectiveness of ProRS inhibitors in multiple myeloma.

5.5 Discussion

Using in vitro MM cell models, this chapter has demonstrated the capability of ProRS inhibitors to kill drug-sensitive and drug-resistant MM cells. This chapter has also confirmed that the AAR is activated in MM cell lines following ProRS inhibition, using bulk RNA-seq. ProRS inhibition activates *ATF4* (the master regulator of amino acid metabolism) and upregulates its downstream targets, including aminoacyl-tRNA synthetases, amino acid transporters, and pro-apoptotic mediators including *DDIT3*. A general shift towards lower protein abundance can also be seen following ProRS inhibitor treatment of MM cells, a hallmark of the amino acid starvation response to halt global protein synthesis. It has also been demonstrated by collaborators that NCP26 and HF elicit GCN2 and eIF2 α phosphorylation in a dose-dependent manner (Figure A.2). During amino acid depletion, GCN2 acts as a cellular sensor by binding uncharged tRNAs and autophosphorylating. Activated GCN2 then phosphorylates eIF2 α [264]. Therefore, GCN2 and eIF2 α phosphorylation indicates canonical activation of the amino acid starvation response by HF and NCP26. Additionally, NCP26R cells, which had

built up resistance to ProRS inhibition, showed decreased expression of *ATF4* and *EIF2A*. Previously, *ATF4* knockdown (but not *ATF3*) has been shown to render tumour cells resistant to amino acid starvation[262]. NCP26R cells also showed significant suppression of ER-associated elements. These transcriptional changes to overcome apoptosis by NCP26 treatment further highlight the AAR and ER stress as mechanisms by which ProRS inhibition kills MM cells.

5.5.1 HF vs NCP26

Excess proline addition has been shown to have no effect on NCP26 treatment of MM cells (up to 20mM of proline), whereas HF's anti-MM effects have been shown to be abrogated by excess proline (Figure A.3). Cancer has been shown to adapt to therapy, changing its gene expression and genetic make-up to overcome drug treatment. In MM, this can also be achieved by the shifting balance of clonal populations, some of which possess advantageous mutations or phenotypes against specific therapies. Therefore, metabolic reprogramming to increase intracellular proline levels would be a very simple way for cancer cells to adapt and overcome HF treatment. As MM cells and the MM bone marrow already possess higher proline levels than normal cells, this could render the effectiveness of HF in MM very short-lived, and patients could become resistant very quickly. NCP26 has demonstrated strong anti-MM effects, whilst not being susceptible to the metabolic liability of a proline supplementation resistance mechanism. Additionally, NCP26 has demonstrated a stark difference between EC₅₀ values of AMO-1 cells and healthy PBMCs (greater than 10-fold)[265], while the EC₅₀s between HF and PBMCs were much closer. Further, NCP26 inhibition in MM in vivo murine models was tolerated without signs of overt toxicity such as weight loss and was effective in reducing tumour growth[265]. This indicates that NCP26 will likely have a much wider therapeutic window than HF, and not exhibit as many of the dose-limiting toxicities and side-effects. This would allow for compounds with a similar mode of action for higher dosing in patients and more effective killing of MM cells, and potentially kill even the most malignant and resistant subclones. NCP26 treatment should perhaps

also be considered for diseases currently being treated with HF, such as Kaposi's sarcoma, autoimmune diseases or fibrotic diseases such as scleroderma.

5.5.2 PIs and amino acid starvation

The capability of HF and NCP26 to overcome resistance in PI-resistant MM (rather than other MM therapies) was investigated due to the similarities in the mechanisms of action of ProRS inhibition and proteasome inhibition. Proteasome inhibition leads to fewer ubiquitin-tagged proteins being degraded, subsequently many misfolded proteins accumulate in the ER lumen. This increases ER stress, activating the integrated stress response and causing the UPR to switch from a homeostatic, pro-survival system to a pro-apoptotic pathway[71, 72]. The UPR shares many mediators with the AAR, for example *ATF4* and *DDIT3*. Therefore, it may be expected that the mechanisms overlap for ProRS inhibition to overcome PI-driven resistance mechanisms. However, it was shown in vitro that HF and NCP26 reduce the cell viability of carfilzomib-resistant L363 cells in a dose dependent manner (Figure 5.3). Accordingly, the underlying mechanisms must be sufficiently distinct for ProRS inhibition to kill PI-resistant cells.

Interestingly, amino acid depletion has been implicated in the mechanism of action of proteasome inhibitors[266]. A study from 2012 demonstrated that treatment of mammalian cells with proteasome inhibitors MG-132 and bortezomib depleted the amino acid pool by decreasing the levels of asparagine/aspartate and cysteine to lethal levels[266]. Using western blots, PI treatment was shown to induce the ISR—evident by eIF2 α phosphorylation and expression of *ATF4*, *DDIT3* and *GADD34*. PI treatment was also shown to phosphorylate and activate GCN2. Supplementation with cysteine and/or asparagine markedly increased cell viability following PI treatment. Cysteine supplementation mostly abrogated the induction of the ISR, without affecting polyubiquitinated protein levels. Cysteine addition also largely reduced GCN2 phosphorylation, thereby establishing that a shortage of critical amino acids induces the ISR via GCN2 and the amino acid starvation response[266].

The group also investigated proteasome inhibition and amino acid depletion in *Drosophila*[266]. Bortezomib (50 μ M) exposure was lethal to *Drosophila*. Bortezomib-treated flies supplemented with excess amino acids saw markedly increased survival, without affecting polyubiquitinated protein levels. Taken together, it is clear that certain amino acids play a cytoprotective role upon proteasome inhibition, and that amino acid depletion is involved in the mechanism of action of PIs. However, the group did not use any MM cell lines or primary MM patient samples in their study. A higher concentration of PI is required to kill healthy cells or non-myeloma cells than myeloma cells, as there is lower baseline ER stress. Therefore, the mechanism of action of PIs in myeloma cells may be different to that of healthy cells or for different cancer cell lines. For example, NF κ B signalling is well established in multiple myeloma pathology, and has been implicated in the mechanism of action of PIs; other cell lines without extensive NF κ B signalling may not react the same way to PI treatment as MM cells. Additionally, due to the massive amount of paraprotein produced by MM cells, they already have increased strain on the proteasome and increased ER stress. Furthermore, the group did not investigate other possible explanations for the induction of the ISR, for example they could have explored the expression of *PERK*, *ATF6* or *IRE-1*, signal activators of the unfolded protein response, another branch of the ISR.

It has previously been shown that during acute amino acid shortages, the proteasome degrades pre-existing proteins to supply amino acids for the synthesis of new proteins, and that proteasome inhibition under these conditions causes rapid AA depletion and markedly impaired translation[267]. Mizrachy-Schwartz et al. (2010) showed that amino acid depletion of Cysteine and Methionine sensitized various cancer cells (including an MM cell line) to proteasome inhibition[268]. Amino acid depletion significantly lowered the IC₅₀s of bortezomib for the cancer cell lines, some of which bortezomib had very little effect on previously in complete growth medium. The group hypothesized that amino acid depletion in combination with proteasome inhibition might improve the effectiveness of PIs in treating myeloma, and might even extend the drug class's applicability to a broader range of cancers.

In this chapter, the combination of PIs and ProRS inhibitors was investigated. Despite evidence of PIs depleting the amino acid pool and amino acid depletion sensitizing cancer cell lines to proteasome inhibition[266, 268], carfilzomib and NCP26 were not found to act synergistically together. They were found to have an additive effect, if not moderate antagonism together. This supports a previous MM study where HF and bortezomib were found to be moderately antagonistic in combination[115]. This may reflect that their mechanisms of action are too similar, whereby both inhibitor classes induce stress responses and pro-apoptotic mechanisms via *DDIT3*. Perhaps this makes having both PIs and ProRS inhibitors in combination redundant, however, as demonstrated in Section 5.2.2 ProRS inhibitors are capable of overcoming PI-resistance in vitro. Therefore, ProRS inhibitors could be used as a replacement for PIs in triplet therapies, once MM patients have amassed significant resistance to PIs. Alternatively, as ProRS inhibitors are capable of overcoming PI-resistance, their additive effect could be beneficial for maximising the number of MM subclones killed and prolonging time until relapse. Full safety profiles of ProRS inhibitors would need to be performed in MM, as both a single-agent and in combination, for both newly-diagnosed patients and for relapsed patients. Relapsed MM patients become more immunocompromised as treatment progresses, so this could perhaps be a barrier in using ProRS inhibitors in RRMM.

5.5.3 Targeting amino acid metabolism

Proline metabolism is thought to be of great importance in tumourigenesis and MM pathology[173, 269]. Although glutamine and glucose serve as the main metabolic substrates for tumour cells, proline as a stress substrate has gained lots of attention due to its unique metabolism, its availability in tumour microenvironments, and various stress-responses[173]. Proline, is the only proteogenic secondary amino acid and has its own metabolic system with its own family of enzymes, distinct from the usual amino acid-metabolising enzymes[173]. Proline metabolism is connected with glutamine metabolism. Cancer cells tend to convert more glutamine to proline compared to healthy cells. Additionally, the bone marrow of MM patients is very

proline-rich and hypoxic. Hypoxia has been shown to increase proline production in vitro. Proline can be used by cancer cells as an energy source under conditions of nutrient stress[270].

The conversion of glutamine to proline consists of several steps. In the final step, pyrroline-5-carboxylate reductase (PYCR) catalyzes the conversion of pyrroline-5-carboxylate (P5C) into proline. Three PYCRs have been identified: PYCR1, PYCR2 and PYCR3. In a recent paper, Oudaert et al. (2022) investigated PYCR enzymes as potential therapeutic targets in MM[271]. The group found that PYCR1 and PYCR2 mRNA expression correlates with an inferior overall survival in MM, and MM cells from RRMM patients express significantly higher levels of PYCR1. Small molecule PYCR1 inhibitor, pargyline, reduced proline production, MM cell viability and proliferation and increased apoptosis. Pargyline increased bortezomib-mediated apoptosis in vitro and enhanced bortezomib sensitivity to reduce tumour burden in a murine model. However, pargyline as a single agent did not alter tumour load. PYRC1 inhibition and silencing resulted in increased CHOP (protein encoded by *DDIT3*) expression, and decreased protein synthesis— suggesting the activation of integrated stress pathways, and possibly the AAR. Inhibiting PYCR1 reduces proline production and its concentration, perhaps this could result in proline depletion and AAR activation, which could be responsible for some of the cytotoxic effects from PYRC1 inhibition. This could also explain why its effects are enhanced in combination with bortezomib, as amino acid depletion seems to sensitize cancer cells to proteasome inhibition[268]. As demonstrated in this chapter, ProRS inhibition of MM cells causes an upregulation of *PYCR1* expression to overcome the perceived proline deficiency. Moreover, downregulated *PYCR1*, *PYCR2* and *PYCR3* expression was seen in NCP26 resistant cells, possibly indicating that the cells have become less reliant on proline and proline metabolism to become more robust to the apoptotic effects of ProRS inhibition. Oudaert's paper supports our work on ProRS inhibition (which mimics amino acid depletion)— both highlighting the effectiveness of targeting amino acid metabolism in MM, particularly proline metabolism. However, the anti-MM cytotoxic effects seen from ProRS inhibition

seem to be far greater than from PYCR1 inhibition as presented by Oudaert et al. (2022). For example, NCP26 treatment alone showed significant anti-tumour activity in a MM mouse model, without significant body weight loss[265]. This could indicate the superiority of the activation of ISR pathways by mimicking proline depletion, whereas PYCR1 inhibition only reduces the concentration of proline sourced from P5C, and not dietary proline or the abundance of proline located in pre-existing proteins which can be catabolised by the proteasome. It would be interesting to see how altering factors of proline metabolism would affect ProRS inhibition, or if HF/NCP26 and pargyline exhibited any synergistic effects together.

In a manuscript currently under review, it was shown by our group (carried out by Dr James Dunford) that numerous inhibitors targeting ProRS, as well as other aaRSs induce significant anti-proliferative effects across multiple MM cell lines (Figure A.4)[265]. Borreloidin, a natural threonyl-tRNA synthetase (ThrRS) inhibitor and CysSA, an aminoacyl adenylate substrate analogue, both reduced proliferative activity of MM cell lines. This shows that the anti-MM effects of HF and NCP26 may not be specific to only ProRS inhibition, and the anti-MM effects may extend to inhibitors of other aaRSs too. Cheng et al. (2018) demonstrated that arginine starvation induced typical ER stress and oxidative stress markers and killed tumour cells[262]. These data further support aaRSs as targets of great importance in MM, and the rationale to develop inhibitors to target them. A full screen of known aaRS inhibitors and substrate analogues against MM would be beneficial, to identify more agents capable of killing MM cells, some of which could be more effective against MM. In [266], MG-132 and bortezomib treatment caused depletion of asparagine/aspartate and cysteine levels, yet proline levels remained fairly constant. It would be interesting to see if AspRS or CysRS inhibitors display any synergy with bortezomib. However, this experiment was not conducted using MM cells. Amino acid levels following PI-treatment of MM cell lines should be investigated first, to see which amino acids are depleted in MM following PI treatment. This could present a whole host of new potential therapeutics in MM.

6

Single-cell RNA-seq analysis of ProRS inhibitors

6.1 Introduction

MM cells grow within the bone marrow and are supported as they grow by their microenvironment. The MM microenvironment comprises a cellular compartment (composed of immune cells, endothelial cells, osteoblasts, osteoclasts and stromal cells) and a non-cellular compartment (composed of the extracellular matrix [ECM], cytokines, chemokines and growth factors)[29, 30] with significant interactions between malignant plasma cells and the surrounding microenvironment. The BM microenvironment has been suggested to play a supportive role in migration, proliferation, differentiation and drug resistance of malignant plasma cells[29, 272]. There is evidence linking the tumour microenvironment to progression of MGUS to active MM, for example significant matrix remodelling has been observed between the bone marrow of healthy individuals, MGUS and MM patients[30]. Therefore, to get an accurate picture of MM, information must be acquired about the surrounding niche.

Historically, the tumour environment has been investigated following the isolation of populations of cells sorted from the tumour and then sequenced using traditional microarray or bulk RNA-seq techniques. Bulk techniques measure the average expression across a sample, which is the sum of cell type specific expression weighted by cell type proportions. Single-cell techniques measure expression for

each individual cell and therefore provide information on cellular diversity that may be lost when pooling cells into bulk samples. Furthermore, multiple myeloma is an extremely heterogeneous disease, this is seen both between patients and within an individual's own tissue. Applying single-cell techniques to capture the inter- and intra-individual heterogeneity is fundamental to identifying molecular and cellular signatures that define MM.

The advent of single-cell technologies has led to a better understanding of the complexity and diversity of the tumour microenvironment. Seminal papers from Melnekoff et al. (2017)[273] and Ledergor et al. (2018)[274] use scRNA-seq to reveal clonal transcriptomic heterogeneity in MM samples. Melnekoff et al. (2017) demonstrated the clonal heterogeneity within MM using samples that were collected from eight relapsed MM patients. The group performed t-SNE clustering analysis and the samples separated into eight transcriptionally distinct clones, each corresponding to a different patient. This highlights the inter-patient differences of MM. Ledergor et al. (2018) performed a similar study to evaluate clonal heterogeneity within MM but also included a set of healthy controls with which to compare the MM group. They found that MM patients have greater inter-individual transcriptional variation, where each MM patient possessed a unique and individual plasma cell transcriptional program. They also showed substantial intra-tumour heterogeneity (subclonal structures) of plasma cells in a third of their MM patient cohort. These papers established the importance of using single-cell techniques to study MM, as to not miss the underlying clonal heterogeneity. However, both of these papers focussed solely on plasma cells and did not look at the surrounding BM microenvironment. To truly understand the complexities of MM and treatment of MM, interactions between plasma cells and the BM niche must also be explored using single-cell techniques.

This chapter uses MM patient-derived BM, from both newly-diagnosed and relapsed patients, to investigate the transcriptional effects of ProRS on MM cells and their surrounding immune microenvironment.

6.1.1 Overview of experiments

Three single-cell experiments, comprising samples from four MM patients, were performed to explore the effect of various compounds (including HF and NCP26) on MM patient tissue. The BM samples for experiments 1 and 2 were obtained from two treatment-naïve, newly-diagnosed MM patients. Experiment 3 comprised samples from two relapsed MM patients, therefore both presenting with a degree of acquired anti-cancer drug resistance. For experiment 1, BM samples were treated for 24 hours with 1 μ M Casin, GSK-J4, HF, NCP26, SGC-GAK, Verteporfin or a DMSO control, totalling 7 samples. For experiment 2, BM samples were treated with 1 μ M CAMKK2, CLK or CSNK2 for 24 hours; 1 μ M SGC-GAK, HF, NCP26 or a DMSO control for 24 and 48 hours, totalling 11 samples. For experiment 3, BM samples from patient 3 and 4 were treated for 24 hours with either a DMSO control, 1 μ M HF, 1 μ M NCP26 or 5 μ M NCP26, totalling 8 samples.

Following compound treatment, scRNA-seq library preparation was performed by Dr Martin Philpott as outlined in Section 3.5.2.

6.2 Data processing

For multiple scRNA-seq datasets to be analysed together and compared, integration of datasets is required. Integration methods identify ‘anchors’ across datasets—cells that are in matched biological state, these cells can then be used to correct for technical variation and batch effects. Initially, all four patient samples (newly-diagnosed and relapsed) were processed and integrated together. However, integration was found to be poor between treatment-naïve and relapsed patient samples. The transcriptome of MM patients has been shown to change considerably following successive rounds of treatment cycles, therefore this could explain the poor integration of BM samples from patients at different points in disease progression. That is, the datasets were too different to identify good anchors between them. Treatment-naïve patient samples (from experiments 1 and 2—patients 1 and 2) were

integrated and analysed together and relapsed patient samples (from experiment 3– patients 3 and 4) were integrated and analysed together.

Experiments 1 and 2 contained numerous samples that were not of interest to this project. Yet, all samples originated from MM patient tissue, therefore all 18 samples were processed by the analysis pipeline, up to and including integration and annotation steps. These samples were included to increase the granularity of the data, and allow for easier annotation of clusters. Accordingly, downstream analysis was only performed for DMSO, HF and NCP26 samples.

6.2.1 Analysis overview

The single-cell analysis pipeline outlined in Section 4.2.3 was used to process the scRNA-seq data. Kallisto BUS/ BUStools was used to pseudoalign reads and quantify gene expression. Next, quality control and filtering of the samples was performed (as per Section 4.2.3), then clustering was performed using Seurat, followed by integration using Seurat and Harmony. Using the Seurat SCTransform normalisation method of integration, the two experiments were too large to integrate across all samples. Therefore, a reference-based approach was taken, whereby a subset of samples were selected (based on their cell richness and relevance to the research question) and listed as ‘reference datasets’ for SCTransform normalisation. Harmony integration was also implemented, using ‘Patient number’ and ‘Experiment number’ as additional covariates.

Cell type annotation was performed with several automated packages (singleR, clustifyr and scClassify), and then fine-tuned manually using a list of known biological markers. No MM classifier or reference was available when performing this analysis (the MM classifier in Section 4.4 was built using these datasets). Therefore, healthy human references were used for annotation. The HumanCellAtlas (HCA) database was used to inform singleR and clustifyr annotation. scClassify was performed in conjunction with a pre-trained scClassify model, based on seven peripheral blood mononuclear cell (PBMC) scRNA-seq datasets (including data from 10Xv2, 10Xv3, smartSeq, celSeq, dropSeq and inDrops). As the reference

datasets were based on healthy tissue, they were unable to label pathological cells, like MM cells. Myeloma cells were identified manually using a range of known markers, for example: *CD38*, *CD138*, *SLAMF7* and *BCMA* (Table A.1).

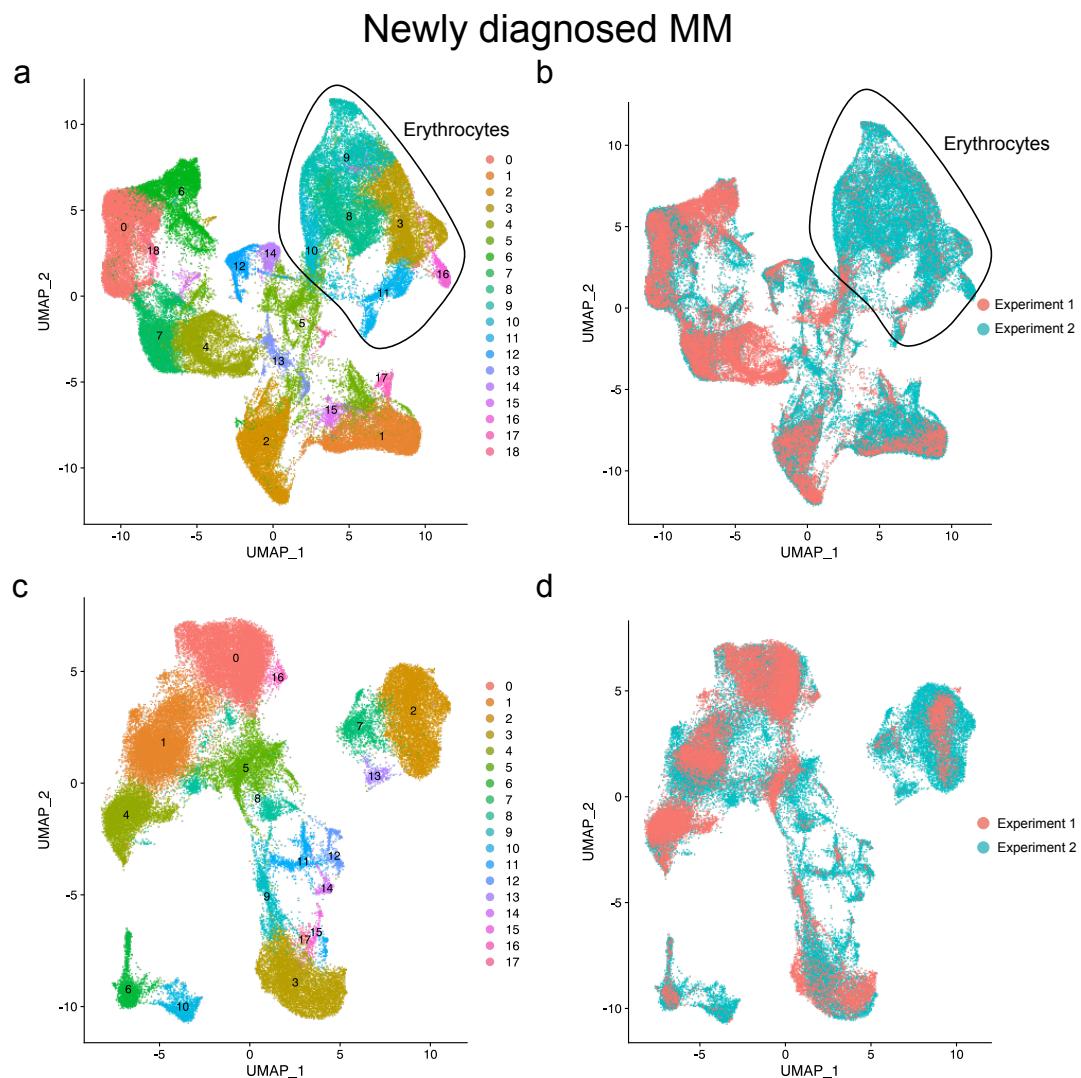

Figure 6.1: UMAP clustering following integration of samples from experiment 1 and 2 (treatment-naïve MM patients). a) and b) Pre erythrocyte cluster and gene removal. Erythrocyte clusters are circled. c) and d) Post erythrocyte removal and re-integration of samples. a) and c) UMAP clustering. b) and d) The composition of each dataset by experiment number.

Experiment 2 was found to have a high erythrocyte population (Figure 6.1a and b). In addition, other cell types were found to be expressing erythrocyte-specific genes, for example MM cells expressing numerous haemoglobin subunit genes. Many of the variable features that Seurat uses for clustering and dimension reduction were

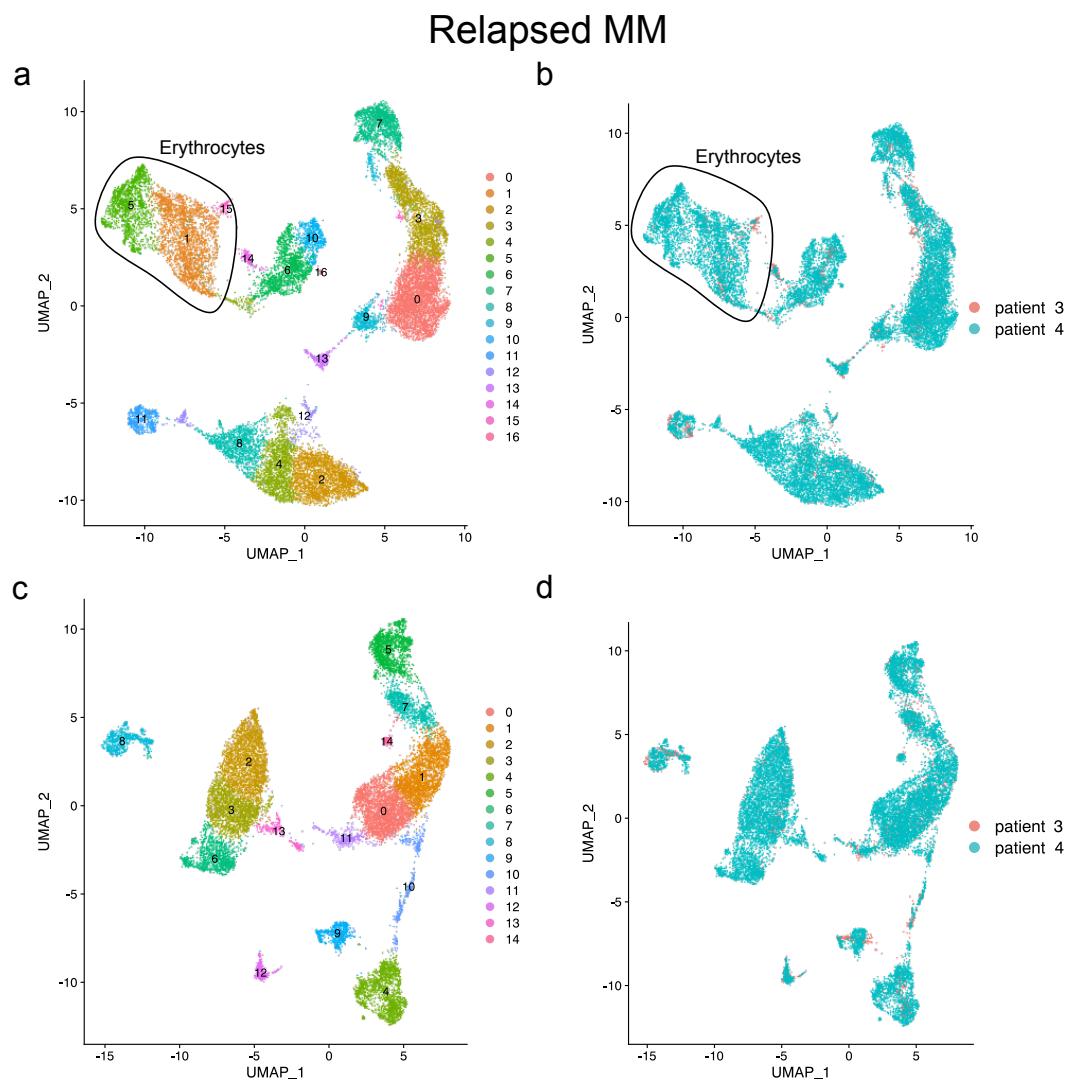

Figure 6.2: UMAP clustering following integration of samples from patients 3 and 4 in experiment 3 (relapsed MM patients). a) and b) Pre erythrocyte cluster and gene removal. Erythrocyte clusters are circled. c) and d) Post erythrocyte removal and re-integration of samples. a) and c) UMAP clustering. b) and d) The composition of each dataset by patient number.

made up of these erythrocyte-specific and haemoglobin genes. The high expression of these genes was found to be affecting the integration of the two experiments together. A theory for the presence of the large number of erythrocytes and un-localised erythrocyte gene expression is that perhaps the BM sample taken for experiment 2 was one of the later samples taken from the patient and contained a large amount of blood. Library prep clean-up may have missed many of these cells, leading to ambient erythrocyte RNA being present within many droplets.

Other MM scRNA-seq studies have observed similar contamination of erythrocyte specific genes, such as *HBB*, *HBA1* and *HBA2*, in non-blood cell populations, despite performing a red blood cell lysis step[275].

It was decided to remove the erythrocyte clusters (clusters 3, 8, 9, 10, 11 and 16 in newly-diagnosed; clusters 1, 5 and 15 in relapsed) and haemoglobin-related genes or erythrocyte-specific genes that were dominating expression in the integrated dataset. After the integrated Seurat object had the erythrocyte genes and cells removed, it was split back up into separate Seurat objects for each sample, and integration and clustering was performed again. Seurat's SCTransform with reference datasets and Harmony (using a multi-covariate model, accounting for each different sample and the two different experiments) were used to re-integrate all samples. Harmony integration was found to integrate clusters across patients and experiments better than using Seurat's SCTransform. The Harmony-integrated datasets were taken forwards and used for cell type annotation and further downstream analyses. Better integration was achieved after removing erythrocytes and erythrocyte-specific genes (Figure 6.1d).

A large erythrocyte component was also found for patient 4 in the relapsed dataset (Figures 6.2a and 6.2b). The same corrective workflow outlined above for the treatment-naïve dataset was applied to the relapsed dataset, removing the erythrocyte cluster and erythrocyte-specific genes and re-integrating using Harmony with samples and patients as covariates.

The total number of cells after each data processing step for each patient and experiment is summarised in Table 6.1. The number of cells originating from patient

Experiment	Patient	Total cells	Cells passing filter	Cell number after erythrocyte removal
Experiment 1	Patient 1	112452	25779	23915
Experiment 2	Patient 2	462560	61059	37161
Experiment 3	Patient 3	4894	2625	2257
	Patient 4	21682	18674	14934

Table 6.1: Total cells, the number of cells passing filter, and the number of cells passing filter once erythrocyte clusters were removed across all samples for each patient.

3 after filtering might be a barrier to interpreting meaningful results. Patients 1, 2 and 4 have sufficient cell numbers to perform downstream analysis, for example investigating differential expression.

6.2.2 Annotation of re-integrated data

R packages clustifyr and scClassify were used to aid in cell type annotation of the integrated datasets, the result of this annotation can be seen in Figure 6.3.

Automated annotation using computational methods gives a good starting point for more detailed manual annotation. Currently, these methods are not a complete substitute for manual annotation using biological knowledge of cell markers. Both cell-type references originate from healthy tissue, therefore the myeloma cluster could not be identified using clustifyr and scClassify with these healthy references alone. Both packages either incorrectly labelled the MM cluster as B cells or were unable to assign any cell type to the myeloma cluster with any confidence and labelled it unassigned. Thus, the MM clusters had to be identified manually using MM biological knowledge. Section 4.4 constructs a MM classifier reference to overcome this problem for future MM scRNA-seq datasets.

Figures 6.4 and 6.5 illustrate MM cell identification for the treatment-naïve and relapsed datasets, respectively, using gene expression of certain MM markers. For MM cells, one would expect to see: expression of *CD38*, but lower expression than in normal plasma cells; high expression of *CD138* in MM cells, as well as high expression of *SLAMF7*, *BCMA*, *KRAS*, *IGKC* and *IGL2*, however these are not exclusive to the MM cluster. You would expect to see little or no expression of *CD45* and *CD19* in the MM cluster and reduced expression of *CD20* in MM cells compared to normal B cells. One may also expect to see expression of *CD56* (*NCAM1*) in abnormal plasma cells, however this is not always detected at the RNA level. Other common markers used to identify MM cells include, *CD81*, *B2M* and *CD117*. Using the expression of a combination of these markers, clusters 2, 7 and 13 were identified as the MM cell population in the newly diagnosed dataset and cluster 4 was identified as MM cells in the relapsed MM dataset.

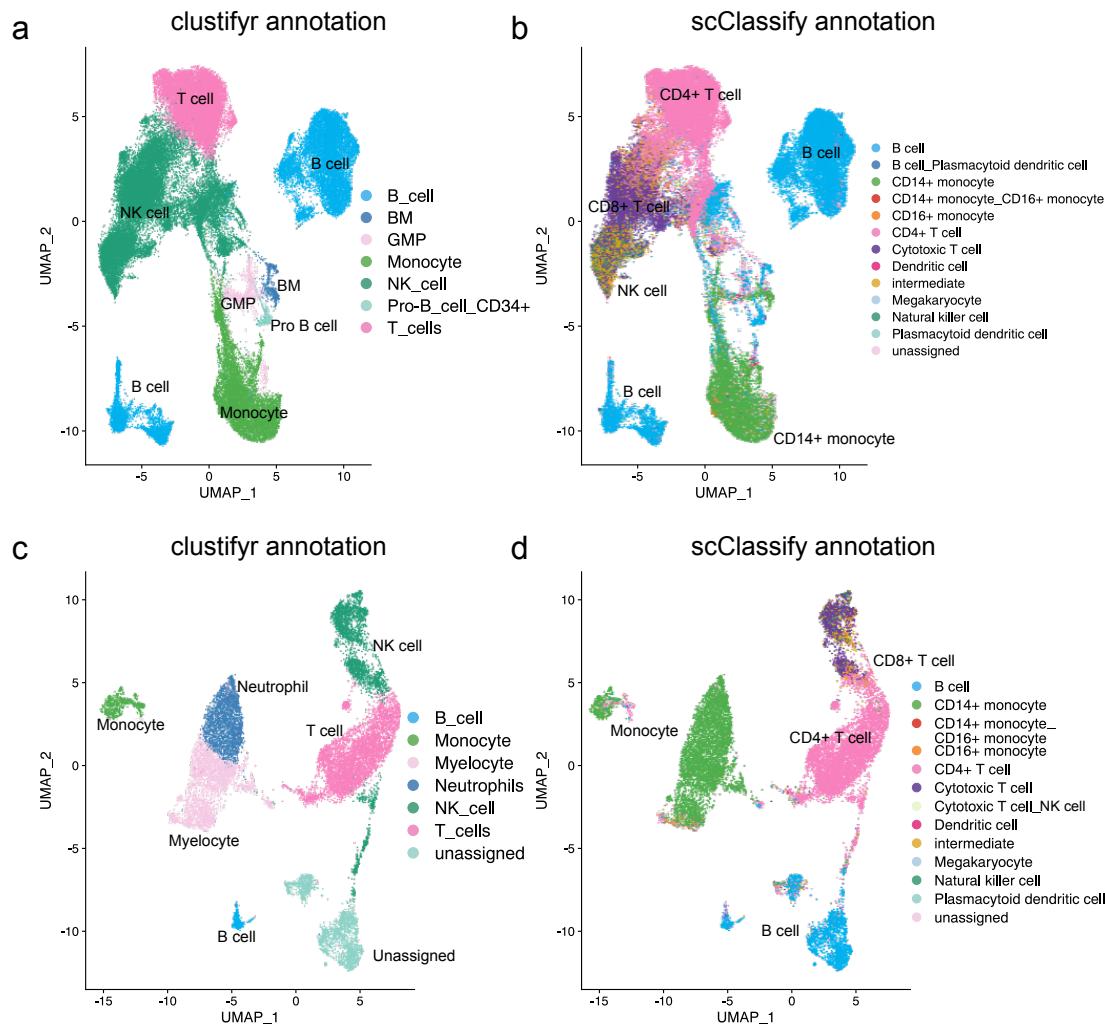

Figure 6.3: Automated annotation of scRNA-seq cell clusters, using the R packages *clustifyr* and *scClassify* in combination with reference datasets. [a, b] newly-diagnosed MM, [c, d] relapsed MM. The output of automated packages *clustifyr* and *scClassify* is used to aid cell type annotation. *Clustifyr* assigns a cell type to each cell cluster, whilst *scClassify* assigns a cell type to each individual cell. *Clustifyr* was used in conjunction with the HumanCellAtlas reference. *scClassify* was ran using a pre-trained model trained on seven PBMC single-cell RNA-seq datasets. Both references originate from healthy data, therefore neither are able to identify the myeloma cell population.

However, from marker expression alone, the identity of clusters 9 and 12 in the relapsed dataset were unclear. Both clusters 9 and 12 seem to belong to a B-cell lineage. Cluster 12 shows increased *CD20* expression, indicating they could be mature B cells. However, clusters 4, 9 and 12 all have an increased expression of *IGKC*, compared to non-B cell clusters. Indicating that perhaps, all B-cell clusters (4, 9 and 12) in the relapsed dataset, may be in fact MM cells. It has previously

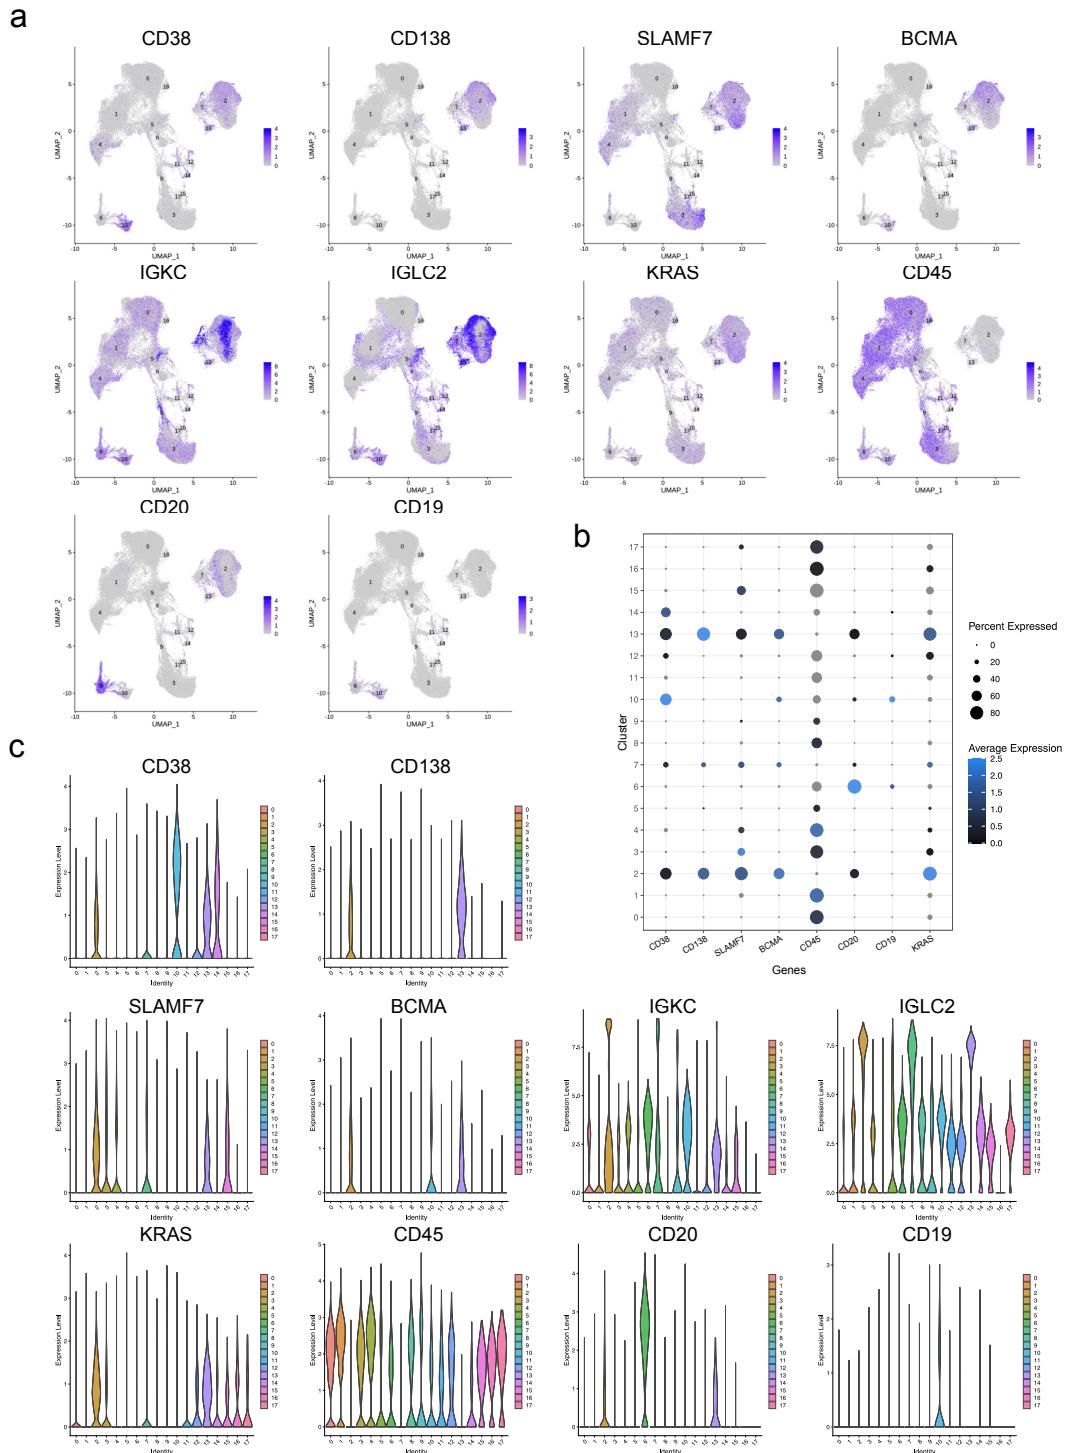

Figure 6.4: Manual annotation of multiple myeloma (MM) cell clusters in experiment 1 and 2 (newly-diagnosed patients) using known MM biological markers. a) UMAP feature plots of MM marker expression. Grey indicates no expression and purple indicates expression. b) A dot plot of the percentage of cells expressing a given marker and the average expression (for each cluster). c) Violin plots of gene expression for each cluster.

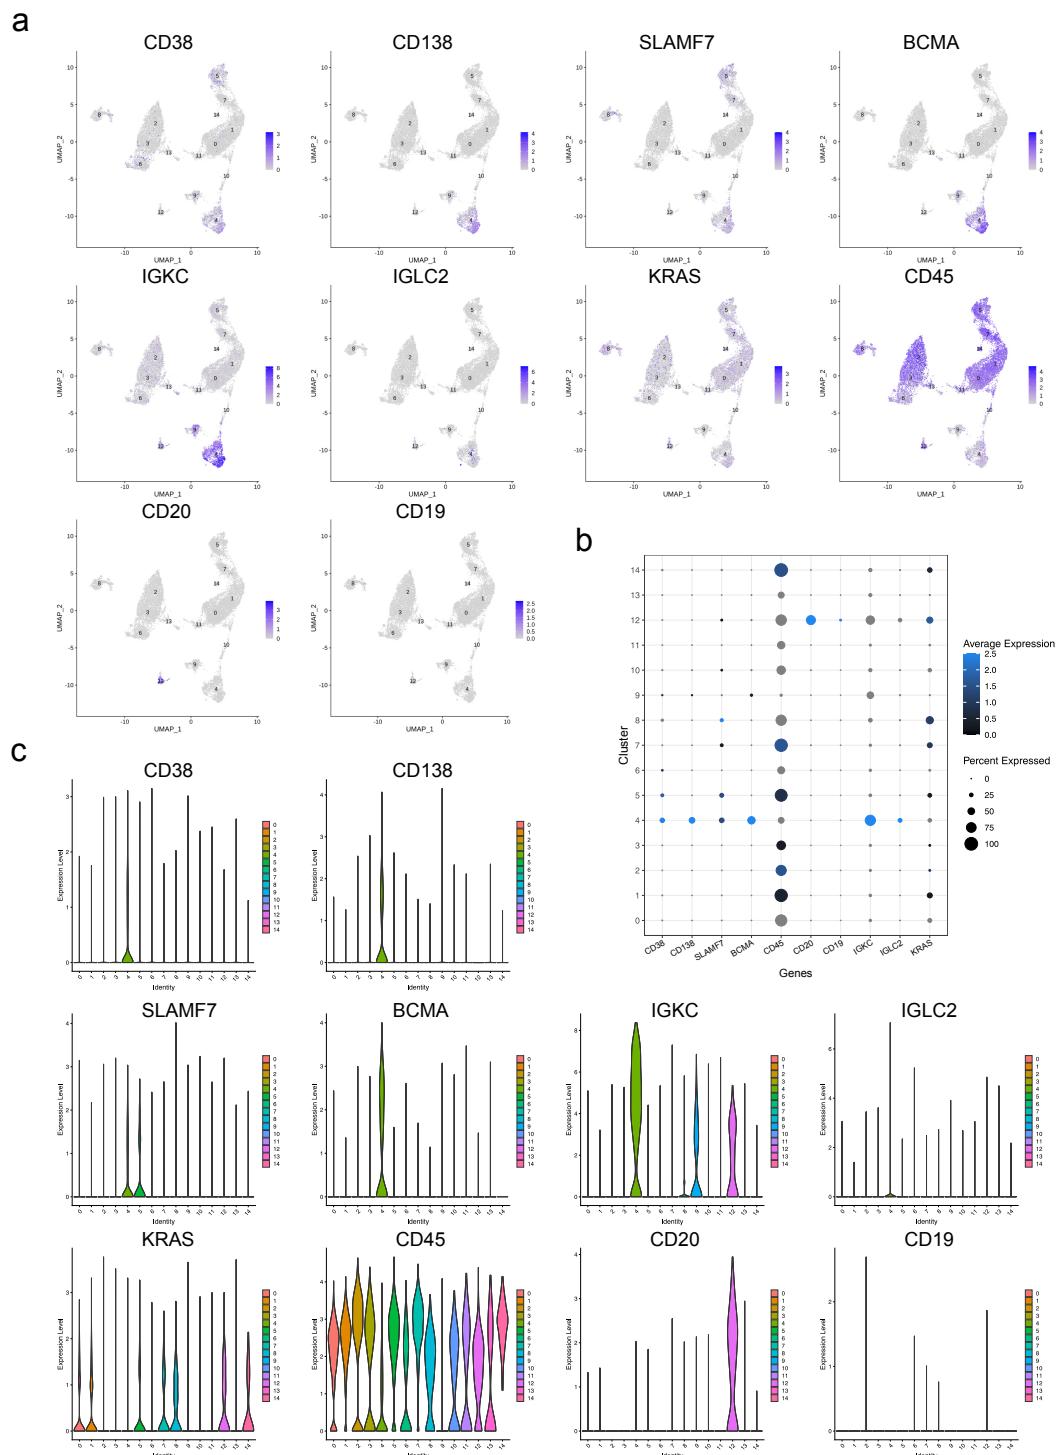

Figure 6.5: Manual annotation of MM cell clusters in experiment 3 (relapsed MM) using known biological markers. a) UMAP feature plots of MM marker expression. b) A dot plot of the percentage of cells expressing a given marker and the average expression (for each cluster). c) Violin plots of gene expression for each cluster.

been shown that MM possess a level of plasticity, that could allow de-differentiation into other cell lineages[276], this may account for the *CD20* expression of cluster 12.

Due to the uncertainty of cell-type identity in the relapsed dataset based on MM marker gene expression alone, inferCNV[197, 198] was employed to detect large-scale chromosomal copy number variations (CNVs) and help inform annotation. The raw counts expression matrix of the relapsed, integrated Seurat object was used as input for inferCNV. ‘Normal’ cells (that is: myeloid cells, T cells and NK cells) were used as a reference for the relative expression intensity of the suspected malignant cell clusters (clusters 4, 9 and 12). A Cutoff value of 0.1 was used for the analysis, to account for the sparsity of droplet-based 3' scRNA-sequencing. Figure

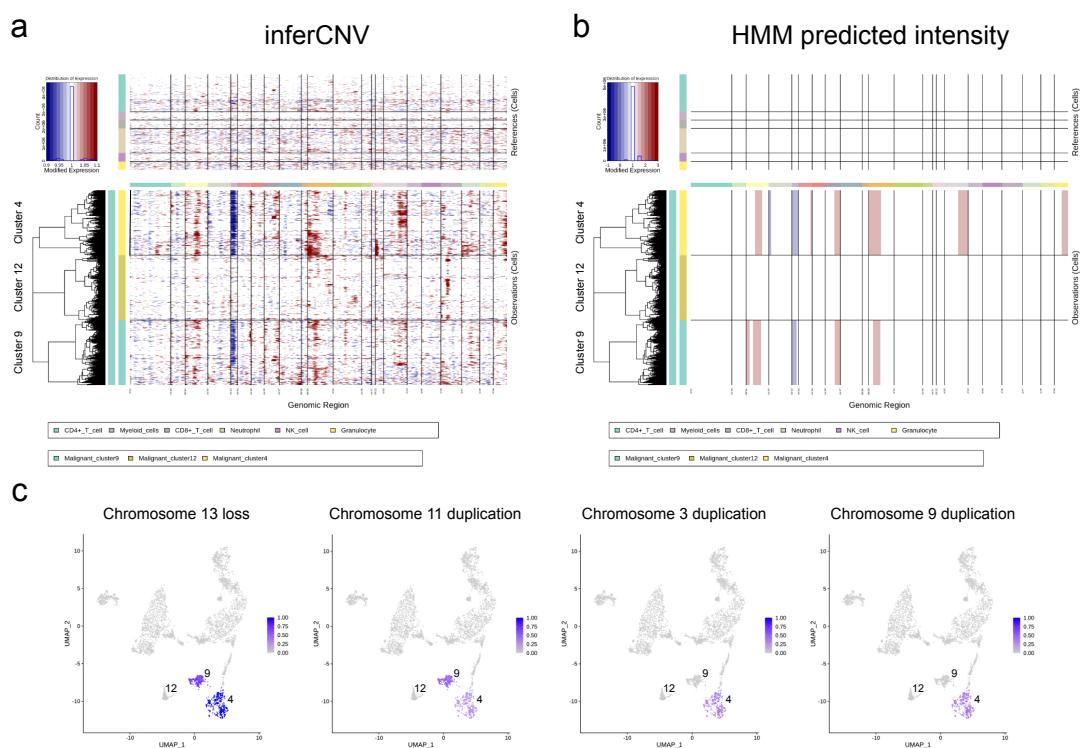

Figure 6.6: InferCNV results for the relapsed MM dataset. [a and b] InferCNV heatmaps. The top panel shows expression values for the reference ‘normal’ cells. The bottom panel shows expression values for the suspected malignant cells (clusters 4, 9 and 12). Red indicates chromosomal region amplifications and blue indicates chromosomal region deletions. a) De-noised inferCNV results. b) Hidden Markov-Model (HMM) copy number variation (CNV) region predictions. Chromosomal deletions predicted for chromosome 13 and chromosomal duplications/gains predicted in chromosomes 11 and 19 for clusters 4 and 9. Gains also predicted in chromosome 3 and 9 for cluster 4. c) UMAP featureplots demonstrating chromosome 13 loss and chromosomes 3, 9 and 11 duplications.

6.6 shows the inferCNV results for the relapsed dataset. Myeloma-defining CNVs were seen in both cluster 4 and cluster 9, including chromosome 13 deletion and duplications of chromosomes 11 and 19. The inferCNV results also demonstrate that there are different genetic MM subclones within the population, as cluster 4 alone shows regional gain of chromosomes 3, 7, 9 and 16. This fits with the <FISH - ask martin for ORBID> data for the relapsed patients, whereby they had chromosome 13 deletions... Therefore, it can be concluded that clusters 4 and 9 are subclonal MM populations.

InferCNV was also employed for the treatment-naïve dataset (Figure A.6) to check for CNVs. The inferCNV results confirmed the gene expression-based identification of clusters 2, 7 and 13 as the MM cell population.

6.3 Results

6.3.1 Newly-diagnosed MM

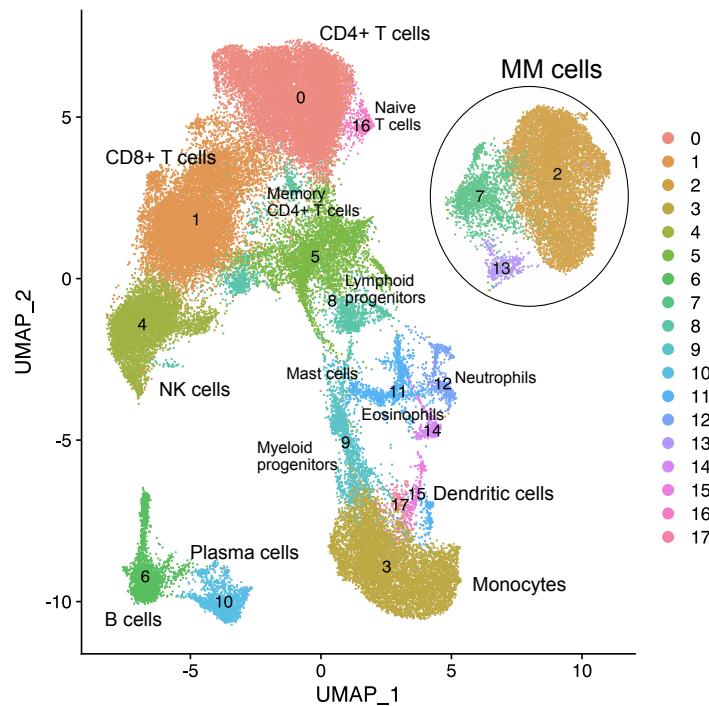

Figure 6.7: Fully annotated UMAP clustering analysis of two newly-diagnosed multiple myeloma (MM) patients. The MM cell population (circled) consists of three distinct clusters.

Figure 6.7 shows final cell-type annotation for the newly-diagnosed MM integrated dataset. 18 distinct clusters were identified using Seurat embeddings. The expected major immune clusters were identified (such as B cells, T cells, NK cells and myeloid cells.) Using the established MM biological markers (shown in Figure 6.4), three distinct MM clusters (2, 7 and 13) were identified.

Composition

Cluster composition analysis by treatment condition is shown in Figure 6.8. Halofuginone treatment at both 24 and 48 hours reduced the proportion of cells in the MM cluster ($p<0.00001$) compared to DMSO, for both experiment 1 and 2. NCP26 treatment at 24 hours reduced the proportion of cells in the MM cluster ($p<0.00001$), for both experiment 1 and 2. HF and NCP26 treatment increased the proportion

of cells in the CD4+ T cell, CD8+ T cell and B cell clusters. Together with dose response curves and cell death assays, this suggests that halofuginone and NCP26 are selectively killing MM cells to a higher degree than other cell types.

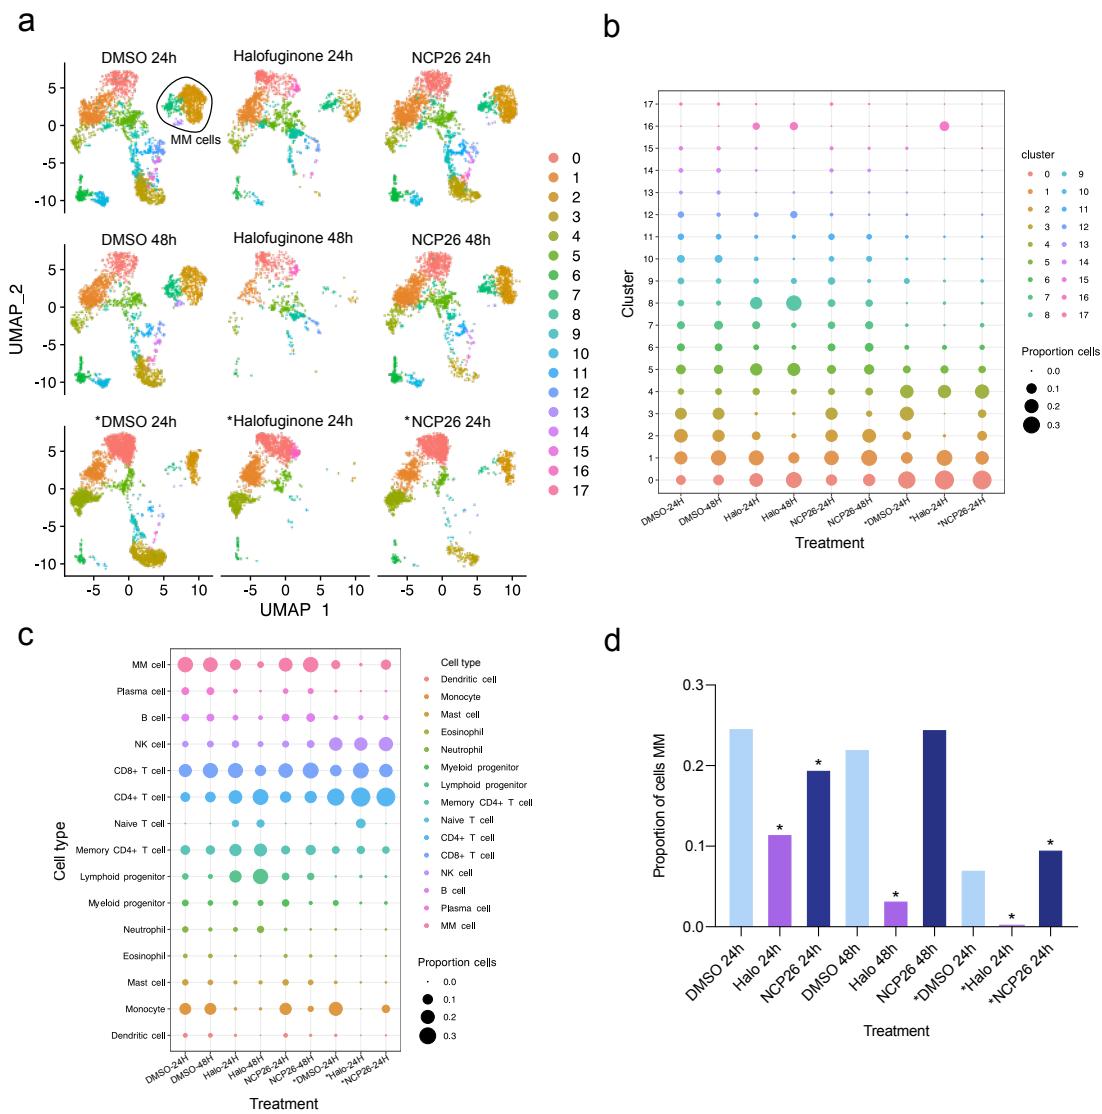

Figure 6.8: Composition analysis of newly diagnosed MM. a) UMAP cell composition plots separated by treatment condition. b) Dot plot showing proportion of cells in each cluster for each sample. c) Dot plot showing proportion of cells in each cell class for each sample (as labelled in Figure 6.7). d) The proportion of cells in the MM cluster only (stars above bars indicate significant at $p < 0.01$ compared to corresponding control). Sample names starting with asterisks originate from experiment 1, no asterisk indicates experiment 2 origin.

Halofuginone treatment and 48-hour NCP26 treatment were also found to reduce the proportion of cells in the monocyte and neutrophil cluster ($p < 0.00001$),

indicating they may have some undesirable off-target effects on myeloid cells.

All of the compounds were used at a concentration of 1 μ M. This is approximately 10 times the concentration of halofuginone's IC₅₀ value on MM cell lines and two times NCP26's IC₅₀ value. As you can see, large number of cells were killed by halofuginone treatment at both 24 and 48 hours. Therefore, the effects seen on the myeloid cells could be due to high dosing of the ProRS inhibitors.

Differential expression

Next, differential gene expression was investigated using Seurat's FindMarkers function. At 48 hours there is substantial cell killing, therefore the 24-hour time point will be mainly focussed on.

Following 24-hour 1 μ M NCP26 treatment, 1515 genes were differentially expressed (DE; p_{adj}< 0.05) in the myeloma cell population in experiment 1, and 1294 genes in experiment 2, compared to DMSO treatment. Figure 6.9 shows the breakdown of DEGs per cell type for NCP26 and HF treatment. 24 hour 1 μ M NCP26 treatment had very little transcriptional effect on many of the other immune cell types, for example T, B and NK cells, where the number of DEGs is an order of magnitude less than for MM cells. This corroborates the composition analysis, where MM cells seem more sensitive to ProRS inhibition than other immune cell types. However, 2016 and 1485 genes were DE in the monocyte cluster following NCP26 treatment in experiment 1 and 2, respectively. This reflects the composition analysis, where the proportion of cells in the monocyte cluster was markedly reduced. This could indicate that NCP26 is not selective for MM cells over myeloid cells.

In MM cells, 73 genes were DE following halofuginone treatment in experiment 1, and 1318 genes in experiment 2. In the composition analysis (Figure 6.8), we saw very few cells remaining in the MM cluster for experiment 1 following HF treatment. Due to the low cell number, there is less statistical power and diversity across the cells, therefore you would likely see fewer statistically significant DEGs for this cluster. Unlike NCP26 treatment, for 24 hour 1 μ M HF treatment we see a large number of DEGs in B, T and NK cell clusters. This likely reflects the differences in

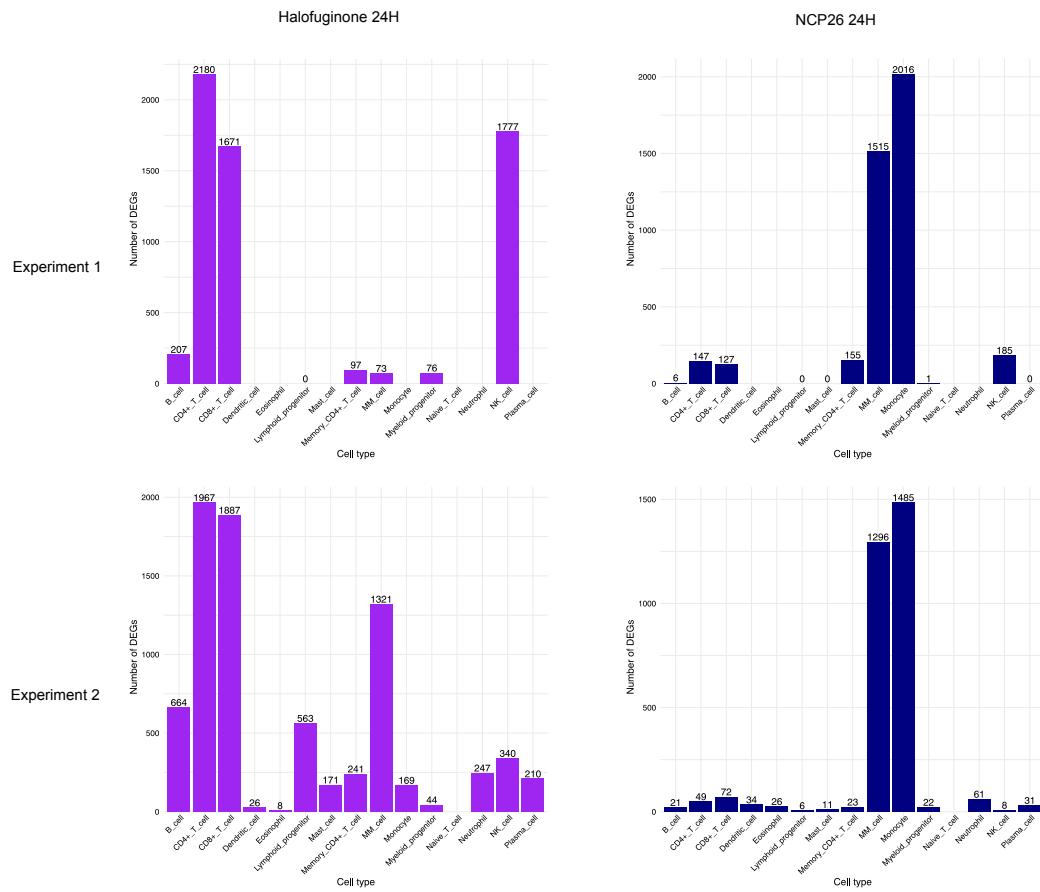

Figure 6.9: Number of differentially expressed genes (DEGs; $p_{adj} < 0.05$) broken down by cell type for two newly-diagnosed MM patients treated with ProRS inhibitors (Halofuginone and NCP26) for 24 hours. Cell type annotation corresponding to Figure 6.7. Experiment 1 and experiment 2 denote separate experiments, each containing BM samples from different newly-diagnosed MM patients.

potency between NCP26 and HF. HF is approximately five times more potent than NCP26. This fits with composition analysis, where HF treatment largely reduced the proportion of cells in the myeloid and MM clusters.

At lower doses (i.e. NCP26 at $1\mu\text{M}$) of ProRS inhibition we see clear evidence of greater transcriptional effects on MM cells and monocytes over other immune subtypes. However at higher doses (i.e. halofuginone at $1\mu\text{M}$) we see substantial cell killing of MM cells and monocytes and larger transcriptional effects on other immune subtypes. This together with the composition analysis, demonstrates that NCP26 and halofuginone are selective for MM cells over most immune cells, except

for myeloid cells. However, this could be a problem with the doses used for treatment. 1 μ M is almost 10 times greater than halofuginone's IC₅₀ and two times greater than NCP26's IC₅₀. This experiment should be performed at a lower concentration to ascertain if NCP26 and halofuginone are more selective for MM cells or monocytes. Ideally, the experiment would be performed over the course of three days at a lower concentration, as in our cell line studies. However, human bone marrow samples do not last very well in extended culture under conditions employed in this study, therefore acute exposure (24 hr) was the preferred method for this experiment.

Pathway analysis

Pathway enrichment analysis was performed for the top 200 upregulated and top 200 downregulated DEGs in the MM cluster, following halofuginone and NCP26 treatment (Figure 6.10).

For NCP26 and halofuginone treatment of MM cells, pathways related to ER-stress and apoptosis were enriched. The unfolded protein response- another member of the ISR, which shares many effectors with AAR- was also enriched. This supports our bulk RNA-seq results that the amino acid starvation response is activated following NCP26 and halofuginone treatment of MM cells.

Figure 6.11 shows a more detailed exploration of AAR gene expression in MM cells and surrounding immune cells. Expression of *ATF4* and its target genes, such as *ATF3*, *DDIT3* and *GADD34*, was increased in MM cells, following HF and NCP26 treatment (Figure 6.11). tRNA aminoacyl synthetase genes (*WARS1* and *SARS1*) were also over-expressed in MM cells following ProRS inhibitor treatment. Figure 6.11b shows selected AAR genes' expression for the entire UMAP clustering plot, separated by treatment condition. HF and NCP26 treatment markedly increased expression of *ATF3* and *TRIB3*, this was localised to MM cells and monocytes. Increased expression of *DDIT3* and *GADD34* can be seen across a few different clusters, however it is most pronounced in the MM and monocyte clusters. Additionally, the apoptotic mediator *TNFRSF10B*, positively regulated by DDIT3, was upregulated in MM cells and monocytes (Figure 6.12b). Indicating

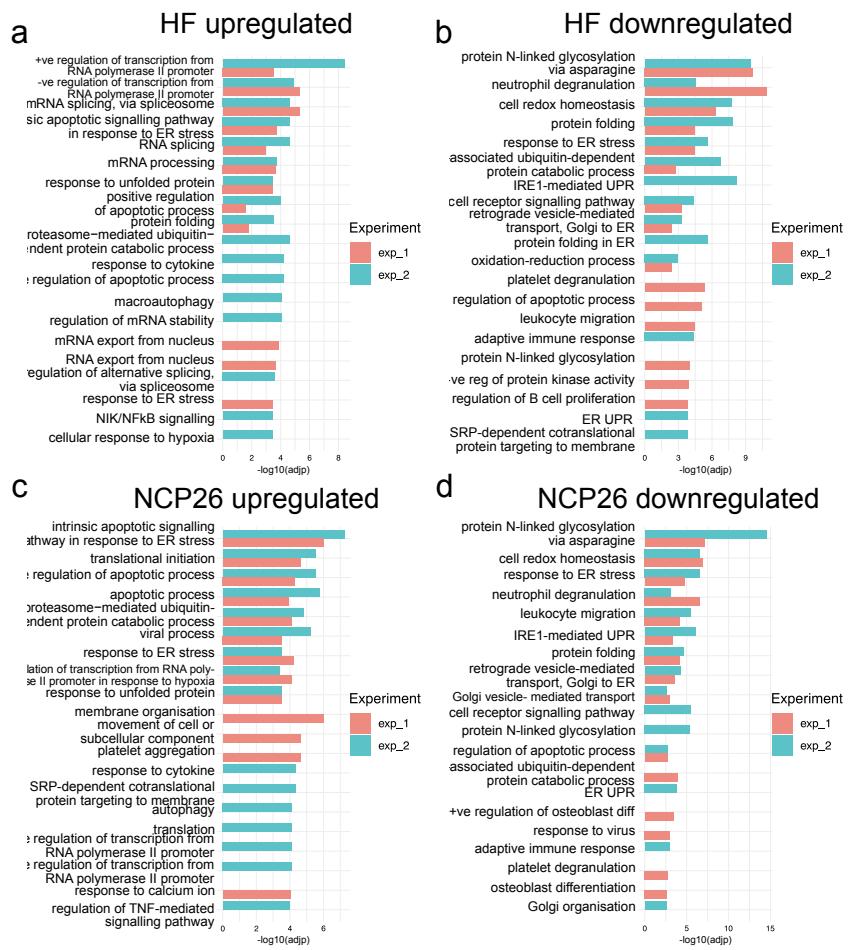

Figure 6.10: Pathway analysis (Gene ontology biological processes; GOBP) of the MM cluster. a) and b) Halofuginone treatment. c) and d) NCP26 treatment. a) and c) GOBP pathway analysis performed using top 200 upregulated DEGs ($p_{\text{adj}} < 0.05$ and $\log_{2}FC > 0$) ranked by fold change. b) and d) GOBP pathway analysis performed using top 200 downregulated DEGs ($p_{\text{adj}} < 0.05$ and $\log_{2}FC < 0$) ranked by fold change.

that, although aaRSs are ubiquitous enzymes and ProRS inhibitors cause some degree of activation of the AAR in all cells, they are cytotoxically more selective for MM cells, and lead to an apoptotic cascade of events, preferentially over other cell types. *CDKN1A* was also overexpressed in MM cells following NCP26 and HF treatment. *CDKN1A* is a target gene of *ATF4* and arrests cell cycle progression by inhibiting the activity of cyclin-dependent kinases. HF has previously been shown to cause cell cycle arrest and to accumulate cells in the G₀/G₁ phase of the cell cycle.

Moreover, Figure 6.12 demonstrates that NCP26 and HF have profound anti-MM effects on MM cells. NCP26 and HF treatment markedly reduce expression of MM

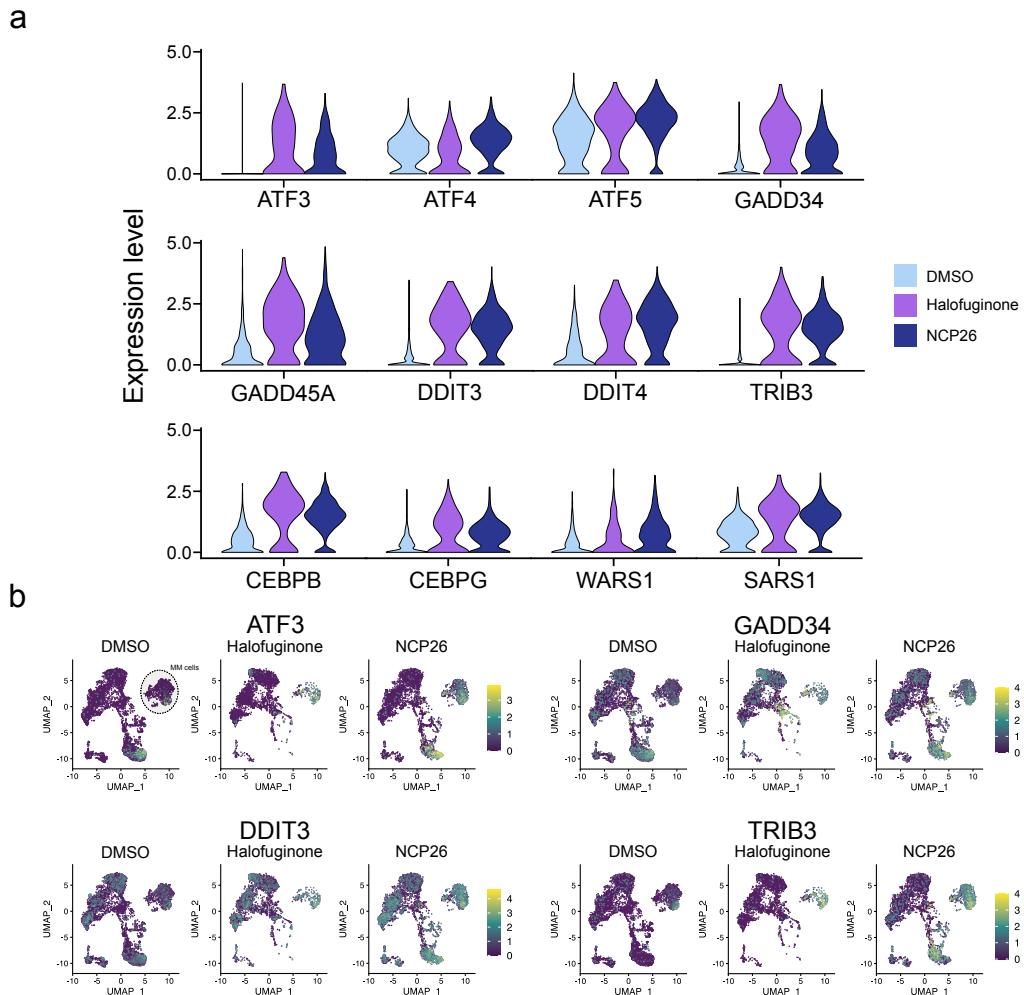

Figure 6.11: A selection of differentially expressed amino acid starvation response (AAR) genes following 24 hour treatment with ProRS inhibitors (newly-diagnosed MM patients). a) Violin plots showing expression of selected AAR genes in the MM population following DMSO, halofuginone and NCP26 treatment. b) Feature plots of UMAP clustering, showing gene expression of AAR genes *ATF3*, *GADD34*, *DDIT3* and *TRIB3*. pathological marker *CD138* in MM cells. Additionally, NCP26 and HF treatment reduced expression of *IGKC* and *IGLC2*, the genes coding for the constant regions of immunoglobulin light chains, Kappa and Lambda. Previously these genes have been implicated in MM outcome.

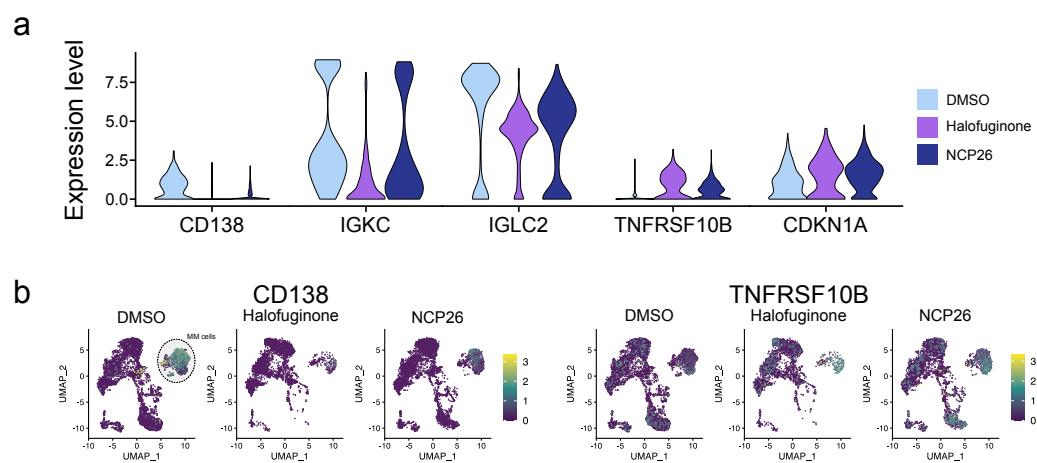

Figure 6.12: A selection of differentially expressed multiple myeloma (MM) and cell cycle/apoptotic markers in newly diagnosed patients treated with ProRS inhibitors for 24 hours. a) Violin plots showing expression of selected genes in the MM population following DMSO, halofuginone and NCP26 treatment. b) Feature plots of UMAP clustering, showing gene expression of MM pathological marker *CD138* and apoptotic marker *TNFRSF10B*. 6.3.2 Relapsed MM

Figure 6.13 shows final cell-type annotation for the integrated relapsed MM patient samples. Substantial transcriptional difference are apparent between the relapsed patients and the treatment-naïve patients, in both their myeloma cells and their immune microenvironment. 15 distinct clusters were identified. The expected major

immune clusters were identified (such as B cells, NK cells, T cells and myeloid cells.) Using the established MM biological markers (Figure 6.5), and inferCNV results, two distinct MM subclones (cluster 4 and cluster 9) were identified. MM cells in cluster 4 were seen to express *CD138* (Figure 6.5). However, MM cells in cluster 9

showed little or no *CD138* expression. As mentioned in Chapter 4, these *CD138*⁻ MM cells are likely to have higher proliferative potential than *CD138*⁺ MM cells. They are also sometimes regarded to have ‘stem-cell’ like clonogenic properties and to be more resistant to chemotherapy than their *CD138*⁺ counterparts[277]. This *CD138*⁻ subclone of MM cells would not have been sequenced if *CD138*⁺ enrichment techniques were used for sorting cells.

Composition

Cluster composition analysis for relapsed MM by treatment is shown in Figure 6.14. 1 μ M and 5 μ M NCP26 treatment reduced the proportion of cells in MM cluster 4 compared to the DMSO control. There is insufficient evidence ($p>0.05$) to conclude if HF treatment affected the proportion of cells in MM cluster 4. However, HF significantly reduced the proportion of cells in the myeloid and B cell clusters. This perhaps indicates that in relapsed MM, halofuginone is not selective for myeloma cells over other immune cells. This may indicate an advantage of NCP26 and proline non-competitive ProRS inhibitors in relapsed myeloma. *PYCR1* (catalyzes the conversion of P5C to proline) expression has been shown to be increased in MM cells in relapsed/refractory MM patients[271], therefore relapsed MM patients may have increased proline concentration in MM cells than treatment-naïve MM patients. Neither ProRS inhibitor reduced the proportion of cells in MM cluster 9.

Differential expression

Next, differential gene expression was investigated for the relapsed MM patients. 1073 genes were DE in MM cluster 4 following 24-hour 1 μ M HF treatment. 157 and 801 genes were DE in MM cluster 4 following 24-hour 1 μ M and 5 μ M NCP26 treatment, respectively. 4, 1, and 3 genes were DE in MM cluster 9 by HF, 1 μ M NCP26 and 5 μ M NCP26 treatment, respectively. Together with the composition analysis, this indicates that the cluster 9 MM subclone may be more resistant to ProRS inhibition than the other myeloma subclone.

The breakdown of DEGs per cell type for NCP26 and HF treatment is shown in Figure 6.15. In contrast to the newly-diagnosed MM data, many of the other

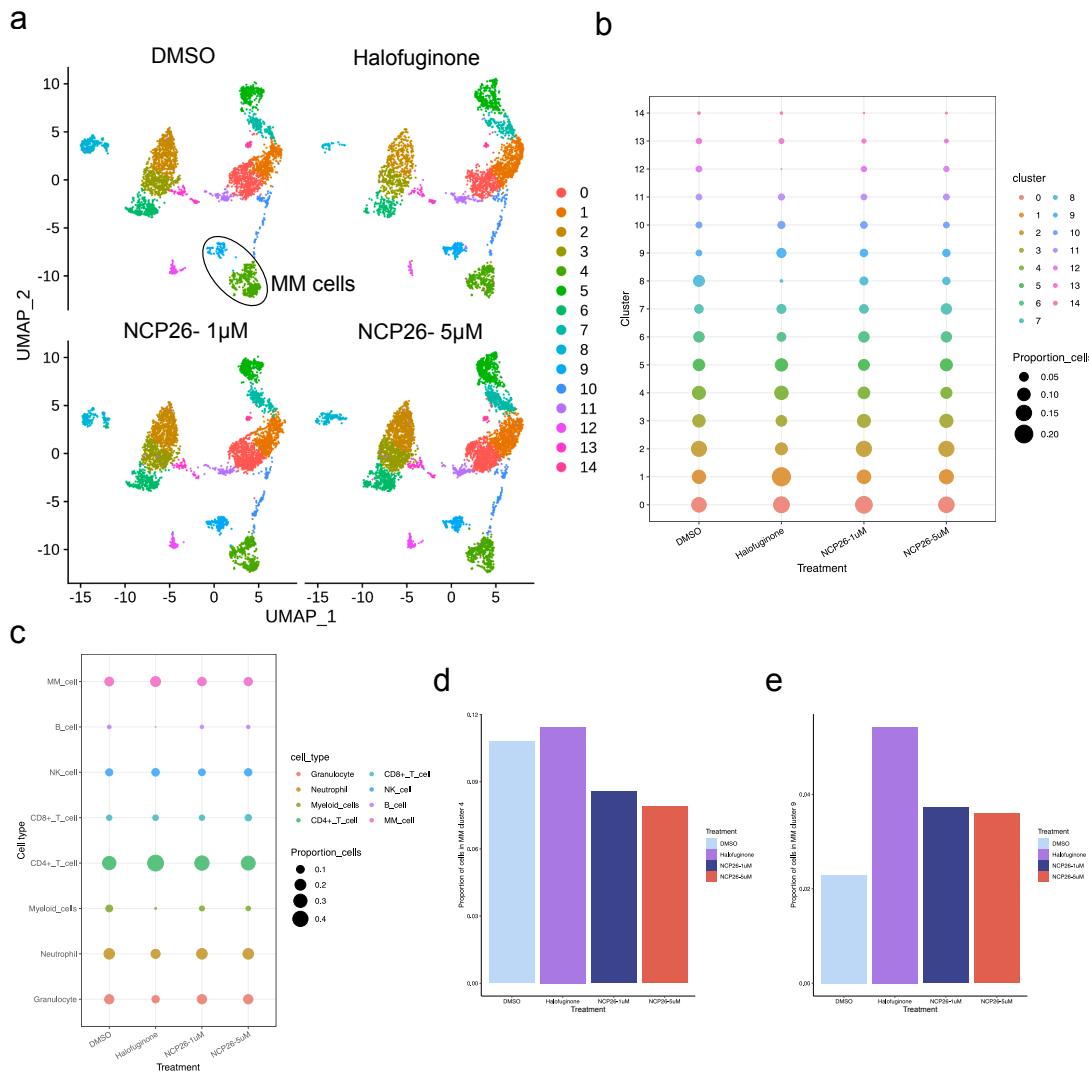

Figure 6.14: Composition analysis of relapsed MM cells treated for 24 hours with ProRS inhibitors. a) UMAP cell composition plots separated by treatment condition. b) Dot plot showing proportion of cells in each cluster for each sample. c) Dot plot showing proportion of cells in each cell class for each sample (as labelled in Figure 6.13). d) The proportion of cells in MM cluster 4 only. immune subtypes are differentially expressed to similar degrees as MM cells by ProRS inhibition. Additionally, there were more DEGs for the myeloid cluster than for MM cells for 1μM and 5μM NCP26 treatment. Myeloid cells have fewer DEGs than cluster 4 MM cells for HF treatment, however Figure 6.14 demonstrates a substantial lower proportion of cells in the myeloid cluster for the HF-treated sample, therefore one may not expect as many statistically significant DEGs for

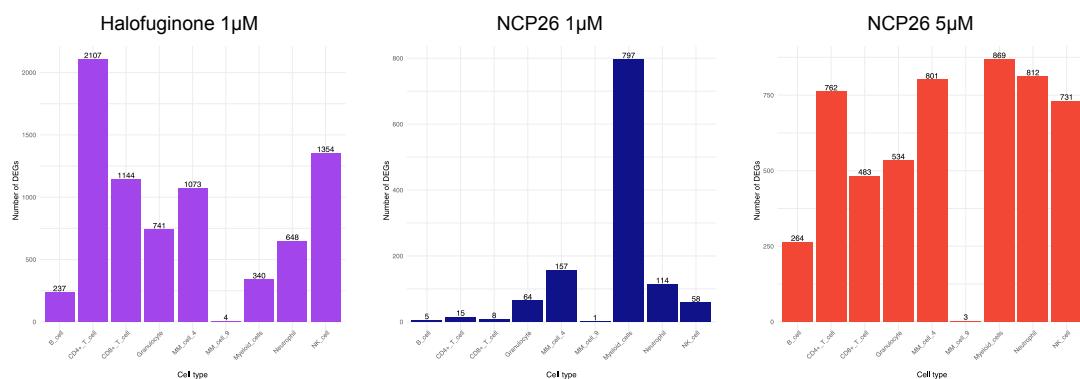

Figure 6.15: Number of differentially expressed genes (DEGs; $p_{adj} < 0.05$) broken down by cell type for a relapsed MM patient (patient 4 only) treated with ProRS inhibitors (Halofuginone and NCP26) for 24 hours. Cell type annotation corresponding to Figure 6.13.

the few cells remaining in the cluster. Under these experimental conditions, it seems NCP26 and HF may not be as selective for MM cells in relapsed MM as they are for newly-diagnosed MM, and that the ProRS inhibitors may not be very effective against some resistant myeloma subclones. However, further experiments with varying dosing conditions and samples from multiple relapsed MM patients would be required to validate this.

Pathway analysis

Pathway enrichment analysis was performed for the top 200 upregulated and top 200 downregulated DEGs in MM cluster 4, following HF and NCP26 treatment (Figure 6.16). Pathway analysis could not be performed for MM cluster 9, as there were too few DEGs. Genes involved in translation, NF- κ B signalling and amino acid metabolism pathways were downregulated following ProRS inhibition (Figure 6.16). Cell death, apoptotic and cell cycle pathways were enriched following ProRS inhibition. This follows the previous chapter and established literature, whereby AAR activation triggers cell cycle changes, cell death and a global reduction in the translational machinery. Interestingly, for all three treatments, mRNA splicing was enriched, indicating a potential spliceosomal mechanism for these inhibitors. mRNA splicing has been implicated in the mechanism of amino acid starvation

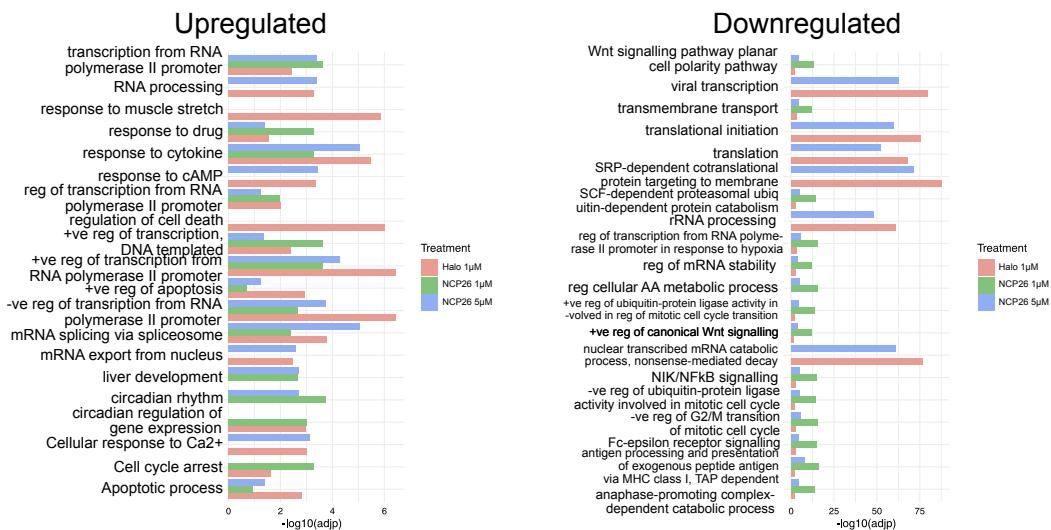

Figure 6.16: Pathway analysis (Gene ontology biological processes; GOBP) of MM cluster 4 in RRMM dataset. GOBP pathway analysis performed using top 200 upregulated or downregulated DEGs for ProRS inhibitor (1μM halofuginone and 1μM or 5μM NCP26) treatment compared to DMSO control treatment for MM cluster 4.

before[278], and that the spliceosomal response to amino acid depletion does not require GCN2 activity.

Figure 6.17 shows AAR gene expression in relapsed myeloma cells, as well as the surrounding immune cells. AAR gene expression in MM cluster 4 follows the typical patterns of ProRS inhibition, as seen in the treatment-naïve dataset and bulk RNA-seq data, increased expression of *ATF3*, *GADD34*, *GADD45A*, *DDIT3* and amino acid transporters, and decreased expression of some AAR-related genes such as *DDIT4*. However, the other myeloma subclone (cluster 9) does not display the typical AAR transcriptional changes following ProRS inhibitor treatment, as seen in previous data. For example, the expression of some AAR genes, such as *ATF3*, *GADD34* and *SLC38A2*, was increased in cluster 9 following NCP26 treatment, however many other AAR gene expression levels were unaffected by ProRS inhibitor treatment. Additionally, the expression of some AAR genes was the inverse to previous data, for example ProRS inhibition caused upregulation of *DDIT4* and *FAU* in cluster 9, where previously HF and NCP26 treatment was shown to cause downregulation of these genes in MM cells. This could represent a cyto-protective effect of the AAR in the resistant MM subclone rather than a pro-death signalling

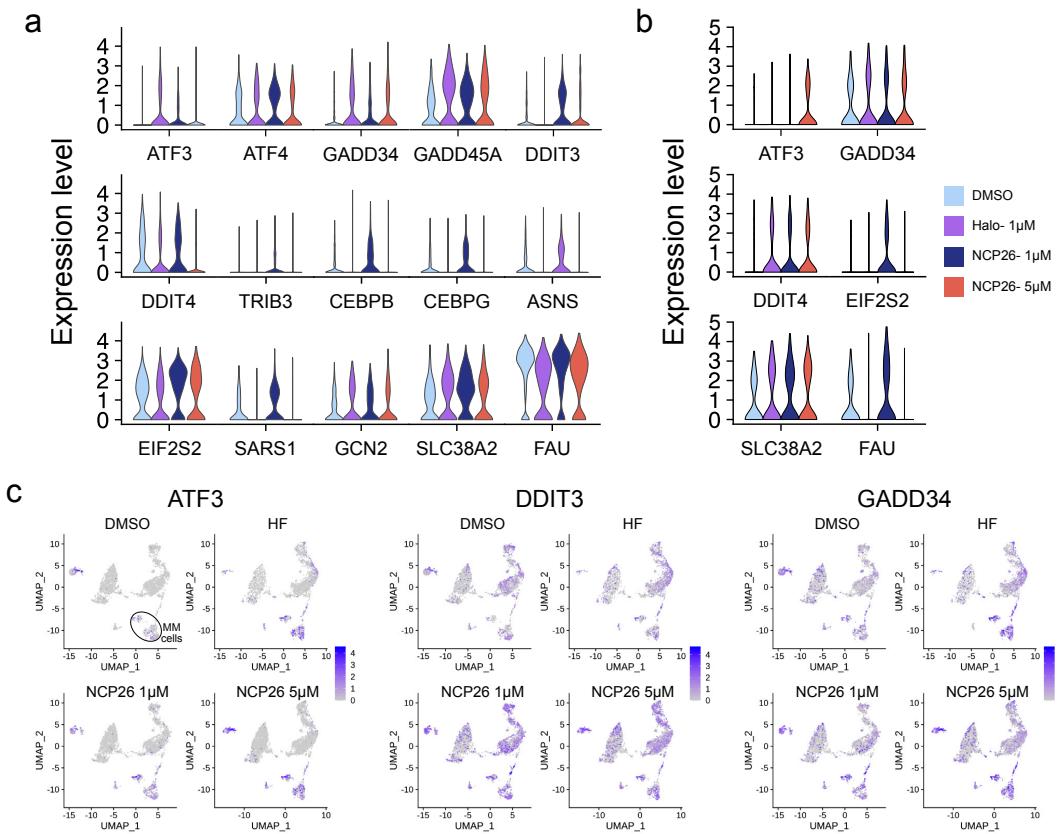

Figure 6.17: A selection of differentially expressed amino acid starvation response (AAR) genes following 24 hour treatment with ProRS inhibitors (newly-diagnosed MM patients). a) Violin plots- AAR gene expression in MM cell cluster 4. b) Violin plots- AAR gene expression in MM cell cluster 9. c) Feature plots of UMAP clustering, showing gene expression of AAR genes *ATF3*, *DDIT3* and *GADD34*. response. In fact, as seen in Figure 6.14e, HF and NCP26 treatment increased the proportion of cells in MM cluster 9.

6.3.3 ProRS inhibitor effect on myeloid cells

From differential expression analysis HF and NCP26 treatment seem to have a large transcriptional effect on myeloid cells, especially monocytes/macrophages. Composition analysis also revealed that ProRS inhibition significantly reduced the proportion of cells in myeloid clusters, in both treatment-naïve and relapsed MM scRNA-seq datasets. Feature plots and violin plots demonstrated that amino acid starvation response effector genes, such as *DDIT3* and *ATF3* were upregulated

in monocytes. However, myeloid cells are non-malignant. ProRS inhibitors were originally thought of as good potential candidates as anti-cancer drugs because tumour cells produce large amounts of protein, and are therefore heavily dependent on translational machinery, like tRNA-synthetase enzymes. This is especially true for myeloma cells, secreting large amounts of M protein. Therefore, it is surprising that ProRS inhibitors seem to be non-selective for MM cells over MM patients' non-malignant myeloid cells.

Pathway analysis

Differential expression and pathway enrichment analysis was performed for NCP26 and HF treatment in monocyte/macrophages. Cell cycle arrest, apoptosis, programmed cell death and stress responses were enriched in ProRS inhibitor treated samples (Figure 6.18 and Figure 6.19). This indicates that the loss of cells in the myeloid cell cluster is due to cell death.

Immune and inflammatory responses were modulated following ProRS inhibition in myeloid cells. Neutrophil degranulation, secretory granule, lysosome, chemotaxis and migration pathways were suppressed in myeloid cells. Additionally, mitochondria-related pathways were suppressed, such as oxidative phosphorylation, the electron transport chain and mitochondrial membrane components. This may indicate some mitochondrial dysfunction in myeloid cells following ProRS inhibition.

6.4 Discussion

This chapter has demonstrated the activation of the AAR and apoptotic mechanisms, as well as other anti-MM effects, following ProRS inhibitors in primary MM patient samples, using scRNA-seq. In newly-diagnosed and relapsed patients, HF and NCP26 treatment elicited a strong transcriptional change and substantial cell death in the MM cell cluster, this was demonstrated using composition and DE analyses. This effect was selective for MM cells over NK cells, T cells and B cells. This follows the original hypothesis that (despite the ubiquity of aaRS enzymes) aaRSs would make a good target in MM, and aaRS inhibitors would be selective for MM cells over benign immune counterparts, due to translational and paraprotein burden on MM cells. However, it has been shown in DE and composition analyses (of a single RRMM patient) that the ProRS inhibitors also seems to elicit apoptosis in myeloid cells. Additionally, in the relapsed dataset, MM cell cluster 9 appears to be resistant to ProRS inhibitors for 24 hour treatment at the given drug concentrations.

6.4.1 Relapsed resistant MM cluster

Clusters 4 and 9 in the relapsed MM dataset were identified as MM clusters using gene expression data and inferCNV analysis. From inferCNV, both clusters were found to have myeloma-defining chromosome 13 deletions. The cells in cluster 9 were shown to express very little or no *CD138*. As discussed in Section 4.5.3, *CD138*⁻ MM cells have been reported to have a higher proliferative potential than *CD138*⁺ plasma cells. Often the presence of *CD138*⁻ MM cells is also associated with poor prognosis. A decrease in *CD138* expression is seen in MM patients with relapsed/progressive disease compared with untreated MM patients[248]. This was corroborated by our scRNA-seq data, whereby there was no *CD138*⁻ MM cell population in the newly-diagnosed MM dataset, but there was for the relapsed MM dataset. Decreased *CD138* expression has previously been associated with reduced sensitivity to the MM drug, lenalidomide[248]. Cluster 9 in the relapsed dataset (with no or little *CD138* expression) was found to be largely resistant to 24 hour treatment of NCP26 and HF treatment at the given concentrations, whereas *CD138*⁺

cluster 4 was sensitive to ProRS inhibition. This suggests that CD138⁻ MM cells may have increased resistance to anti-MM drugs. However, this experiment only looked at 24-hour ProRS inhibitor treatment, for only two relapsed MM patients. Many MM scRNA-seq studies (such as Cohen et al. 2021, which researched MM drug-resistance pathways[237]), use CD138⁺ plasma cell enrichment techniques prior to sequencing. Thereby, the researchers likely missed subclonal MM populations, which may have been contributing greatly to resistant mechanisms in MM. More MM researchers, especially those interested in drug resistance mechanisms, should sequence the whole BM niche, not just the CD138⁺ fraction. The MM classifiers generated in Chapter 4 can simplify the process of MM cell identification computationally, so that researchers are less reliant on CD138⁺ enrichment techniques.

Differential expression analysis of relapsed MM subclonal clusters (cluster 4 vs cluster 9) revealed signature markers of drug-resistanceA.7. Genes involved in the unfolded protein response pathway were suppressed, as well as ER-associated genes. This is a known mechanism action of PIs, therefore it makes sense that the UPR is modulated in patients that have been treated with PIs previously then relapsed. The execution of phase of apoptosis was also negatively regulated, indicating cells in cluster 9 are more resistant to apoptotic signals.

6.4.2 Effect on myeloid cells

From the results it is clear that, at the given concentrations, NCP26 and HF 24-hour treatment adversely affected monocytes and macrophages. ProRS inhibition elicited a strong transcriptional response, and the myeloid cell cluster was significantly reduced following treatment. Additionally, from DE analysis and pathway enrichment analysis, genes involved in apoptotic mechanisms and cell cycle arrest were enriched, indicating that the reduction of cells in the myeloid cluster was due to cell death.

Previously, Leiba et al. (2012) demonstrated HF's selectivity for MM patients' CD138⁺ tumour cells over PBMCs from healthy donors[115] using a cytotoxicity assay at the range of 25-200nM. This is a significantly lower concentration of HF than used in the scRNA-seq experiments (1μM), so this could represent dosing

differences. However, it must also be noted that Leiba et al. (2012) did not separate PBMCs into their respective subtypes prior to performing the cytotoxicity assays. As demonstrated in this chapter, HF treatment has very little effect on B, T and NK cells. Monocytes only make up approximately 5-10% of the cells found in PBMCs- therefore, the effect of HF on myeloid cells could have been missed due to the minimal effects on the other cell types making up the majority of PBMCs. Furthermore, the control PBMCs originated from healthy donors and not from MM patients. The immune microenvironment of MM patients has been shown to be substantially altered and impaired compared to healthy individuals[279], meaning that using healthy PBMCs as a control for the selectivity of HF may not be entirely appropriate. To truly determine the cytotoxic selectivity of ProRS inhibition for MM cells and myeloid cells, cytotoxic assays must be performed in parallel for MM cells and myeloid cells originating from MM patients.

Wang et al. (2020) investigated the use of halofuginone to treat the inflammatory disease chronic periodontitis[280]. Using a mouse model of chronic periodontitis, they demonstrated that HF treatment significantly reduced the expression levels of pro-inflammatory cytokines, for example IL-1 β , IL-6 and TNF- α . HF treatment was also shown to reduce the total percent of infiltrating immune cells and myeloid cells in gingival tissues when compared with those in control, PBS-treated mice. The percentage of myeloid cells making up the CD45 $^{+}$ fraction of cells in gingival tissue was reduced by approximately 40%, following HF treatment. The authors demonstrated that HF treatment did not affect the cell viability of BM-derived osteoclast precursors cells (that is monocytes and macrophages). However, cell viability was investigated with concentrations of HF ranging from 10pM to 100nM, so perhaps myeloid death is reserved for higher doses of HF treatment. The scRNA-seq experiments used 1 μ M HF, so this may be the concentration levels required to observe ProRS inhibitory effects on myeloid cells.

Previously, the proteasome inhibitor MG132 was shown to induce macrophage apoptosis[281]. A number of proteasome inhibitors have been approved for use in multiple myeloma, in both newly-diagnosed and relapsed MM, and they are

regarded as part of the cornerstone for modern MM treatment. Macrophage apoptosis has not been a barrier in the use of PIs in MM, therefore myeloid cell death may not limit the usage of ProRS inhibitors in the clinic. As discussed in the previous chapter, amino acid depletion has been implicated in the mechanism of action of proteasome inhibitors. Wang et al. (2021) asserted that macrophage apoptosis following MG132 treatment was due to promoting ROS production and mitochondrial dysfunction[281]. As shown above, ProRS inhibition in myeloid cells resulted in suppression of several mitochondrial pathways, as well as induction of oxidative stress. Therefore, mitochondrial dysfunction may play a role in the adverse effect of ProRS inhibition on myeloid cells.

GCN2 has been shown to have an important role in myeloid cell homeostasis and immune function[282, 283], it has also been suggested to be a critical mediator of apoptosis vs autophagy during inflammation. Targeting amino acid metabolism and GCN2 function in myeloid cells, has been suggested as a great potential clinical target[284]. One of the many roles of macrophages is clearance of apoptotic cells[285]. In the presence of apoptotic cells, significant induction of *DDIT3* expression, ATF4 protein, increased phosphorylation of eIF2 α and metabolic stress has been observed in macrophages[283, 286]. This response was not elicited in the absence of GCN2[283], perhaps indicating that the presence of other apoptotic cells (such as apoptotic MM cells) may further activate GCN2 and AAR signalling in myeloid cells. If this were the case, it would explain why in isolated toxicity studies no selectivity is shown for myeloid cells, and why myeloid cells are more sensitive to ProRS inhibition than other immune cells.

The effects of ProRS inhibition in myeloid cells should be examined in more detail. The degree of myeloid suppression from ProRS inhibition should be investigated in CD14+ cells collected from numerous MM patient blood samples (less invasive than bone marrow samples). Preferential selectivity of ProRS inhibitors for MM cells should be confirmed using dose-response experiments, using MM cells and MM patient-derived immune cells, separated into their constituent cell types. These experiments should be performed with and without apoptotic cells present. It would

also be interesting to see if the effect of ProRS inhibition on myeloid cells extends to healthy individuals or other disease pathologies. Moreover, the mechanism underlying cell death in myeloid cells should be elucidated. The role of mitochondrial dysfunction in ProRS inhibition should be explored. Another avenue to investigate could be the suppression of immune/inflammatory pathways seen in myeloid cells following HF and NCP26 treatment. Additionally, the non-canonical functionality of EPRS should be investigated. HF and NCP26 inhibit the proline domain of the bifunctional aaRS EPRS. EPRS is a member of the MSC. EPRS is released from the MSC in myeloid cells upon IFN- γ stimulation, which causes a two-step phosphorylation of two serines in the linker region of human EPRS[130]. EPRS combines with other proteins (NSAP1, L13a and GAPDH) to form the GAIT complex, which represses translation of numerous inflammatory-related transcripts[131]. IFN- γ signalling has been implicated in the mechanism of action of ProRS inhibitors[287]. Therefore, this non-canonical functionality of EPRS could play a role in ProRS inhibition's mechanism of action and could potentially explain the cytotoxic-selectivity of HF and NCP26 for myeloid cells. For example, the formation of the GAIT complex could plausibly affect availability of ProRS for its canonical function. It would be interesting to see if other aaRS inhibitors, (acting on other aaRSs which do not engage in GAIT complex non-canonical functionality), have a similar effect on MM and myeloid cells to determine if the non-canonical functionality of EPRS plays any role in the mechanism of ProRS inhibitors.

A decrease in the number of functional myeloid cells could lead to myeloid suppression (myelosuppression/ bone marrow suppression/ immunosuppression), which in turn makes patients more susceptible to infection. As MM is a disease of elderly people, new therapeutics must be tolerable for patients and not excessively immunosuppressive, especially if they are used to treat RRMM patients, who have increased bone marrow suppression. Substantial myelosuppression can also dictate the dosing regimen of a drug- to balance the efficacy of the drug with the associated side effects and infection risk. However, from in-vivo MM xenograft murine models[265], the mice tolerated NCP26 treatment well, with no signs of

overt toxicity such as weight loss. This indicates that the effect of ProRS inhibition on myeloid cells may not even be an issue in-vivo. Furthermore, myelosuppression is a common side effects of many other cancer therapies, especially in the treatment of hematologic malignancies. Therefore, it would be unlikely that ProRS inhibitor myeloid cell killing would constrain its clinical use in MM.

6.5 Future directions

This work has demonstrated the effectiveness of ProRS inhibition in MM using both MM cell lines and primary patient BM samples, and accordingly presents a novel therapeutic target in MM. Further pre-clinical validation of aaRS inhibition in MM is required. The aim of pre-clinical studies is to demonstrate the effectiveness of a target in a disease model prior to moving to human testing. These models aim to recapitulate the disease as accurately as possible, and in the case of MM, provide insights on the interactions between malignant cells and the surrounding microenvironment. The scRNA-seq experiments in this work constitute samples from four MM patients, two of whom are newly-diagnosed and two of whom have relapsed. Considering MM is an extremely heterogeneous disease, this small sample size does not reflect the total variation seen in MM in the wider population. Additionally, only acute treatment of ProRS inhibitors over 24 hour and 48 hour periods was studied. More scRNA-seq experiments should be performed with varying dosing conditions, with BM samples from many more patients.

In the clinic, treatment cycles often last between four and six months. Our scRNA-seq methodology is limited by the duration human BM samples last in culture. The in-vivo murine model used in [265] to test NCP26 demonstrated that NCP26 was well tolerated for up to six weeks— a significantly longer continuous exposure time than we managed for scRNA-seq. However, mouse models aren't without their limitations. For example, severe combined immunodeficient (SCID) mice (as used in [265]) have a genetic immune deficiency that means they lack B and T cells, allowing for xenoengraftment of human tissue. This means that the effect of compounds on B cells and T cells cannot be monitored. Moreover, subcutaneous

injection of MM cells means that the MM cells proliferate in the absence of the bone marrow microenvironment[288], which supports the development, migration, proliferation and differentiation of malignant plasma cells, as well as contributing to acquired anti-cancer drug resistance. Thereby, not modelling a key factor in MM pathology. However, this model does allow for easy monitoring and measuring of tumour size during treatment. Each mouse model platform has its own strength and weakness, so it is important to select the right model for each specific pre-clinical research question. Recently, in a pre-print by Khan et al. (2022) a new step-wise, directed-differentiation protocol was described to generate 3D, vascularised BM organoid structures, which capture key features of human BM (stroma, lumen-forming sinusoidal vessels and myeloid cells)[289]. This platform supports growth of primary cells from blood cancer patients and would allow for ex-vivo mechanistic studies of MM cells and their interactions within a human BM-like milieu[289]. MM cells that had been cryopreserved and thawed prior to use were shown to rapidly lose viability when plated in-vitro, however, were sustained by the organoid platform for more than 10 days[289]. Several other 3D ex-vivo BM niche models for MM have been proposed[290, 291]. Utilisation of these platforms would allow for investigation of ProRS inhibitors within a MM BM microenvironment (with all relevant immune cells), for longer exposure time than our previous methodology would allow.

Prior to clinical application of ProRS inhibitors, a lead compound should be developed to target ProRS, that shares NCP26's proline-uncompetitive mode of action. NCP26 has the properties of a good chemical tool: its biological target is well-defined (ProRS), it demonstrates selectivity, and it has $< 1\mu\text{M}$ target potency for cell-based assays. However, drugs which are used in the clinic have many other requirements in terms of their pharmacokinetics, pharmacodynamics, and bioavailability. Therefore, a compound is required which targets ProRS, but also has drug-like properties. NCP26 was well tolerated in a murine model, so might be a good drug candidate for clinical use, however its pharmacokinetic and pharmacodynamic properties need further investigation.

Borrelidin, (ThrRS inhibitor) and CysSA, (cysteinyl adenylate substrate analogue) were both shown to reduce proliferative activity of several MM cell lines[265]. The effectiveness of other aminoacyl tRNA synthetase inhibitors should also be tested in MM. This could present a whole new set of potential therapeutics to treat MM. Moreover, some could be more effective or appropriate in MM, with different characteristics or side-effect profiles. aaRSs with different non-canonical functions could present differently. Compound screens for all known aaRS inhibitors should be conducted across numerous MM cell lines.

Prolyl-tRNA synthetase (ProRS) is an enzyme which catalyzes the coupling of tRNA^{pro} to proline, therefore the effect of ProRS inhibitors on tRNAs is of great interest. Additionally, transfer RNA-derived small RNAs (tDRs) have been shown to play pivotal roles in stress responses[292]. tRNA-seq should be performed for ProRS inhibitor treated MM cells and ProRS inhibitor resistant cell lines. tRNA analysis introduced in Chapter 4 would then be used to analyse the resulting data. tRNA charging should also be investigated for ProRS inhibitors, to confirm the mechanism of action upstream of GCN2 phosphorylation and activation of *ATF4* target genes. The proportion of charged and uncharged tRNAs for ProRS inhibitor treated MM cells could be calculated by performing a qPCR-based experiment. This constitutes a future area of research to understand the effects of ProRS inhibitors on a molecular level.

Appendices

A

Supplementary figures

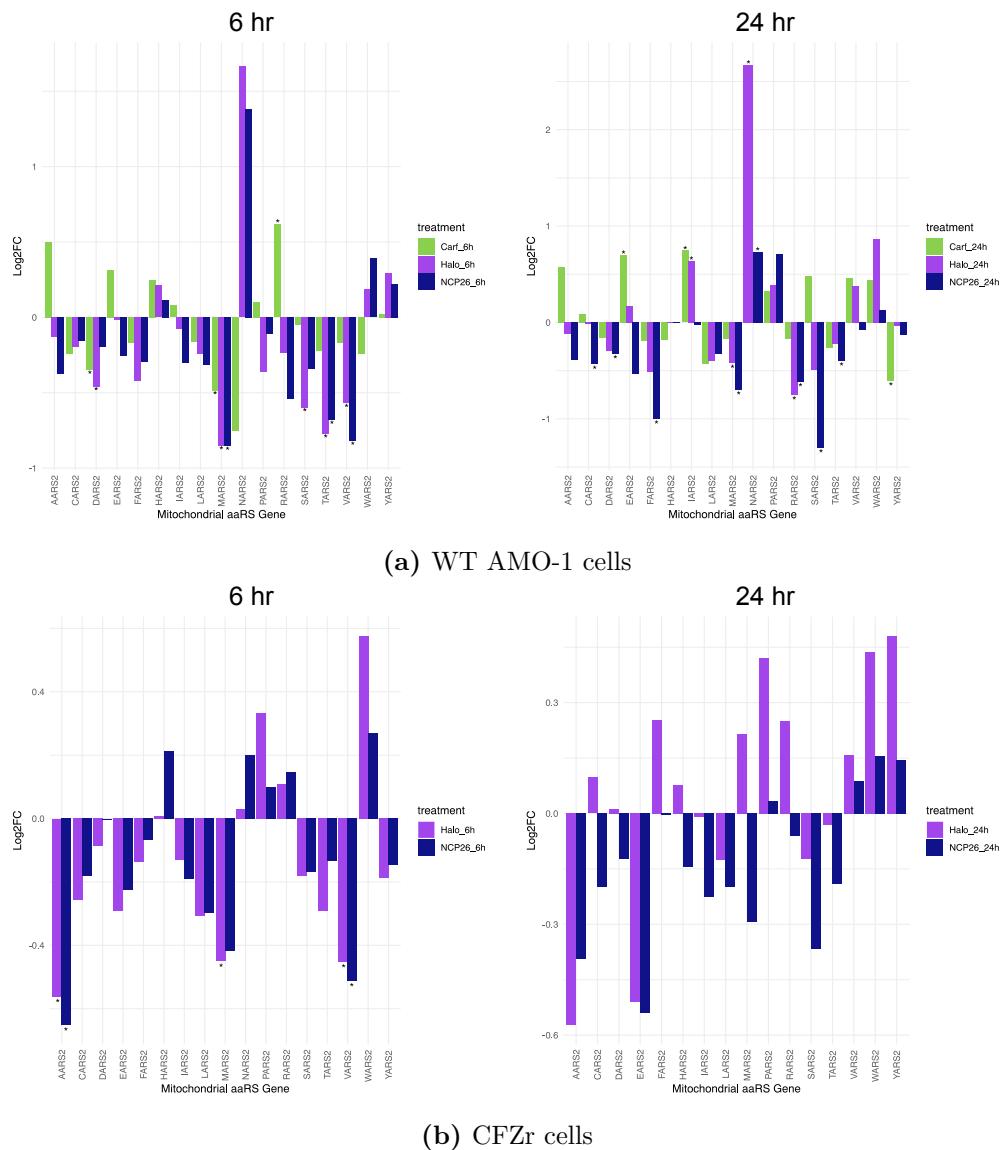

Figure A.1: Mitochondrial aaRS gene expression change ProRS inhibitor/carfilzomib treated vs DMSO control. Stars indicate significance at adjusted p-value < 0.05.

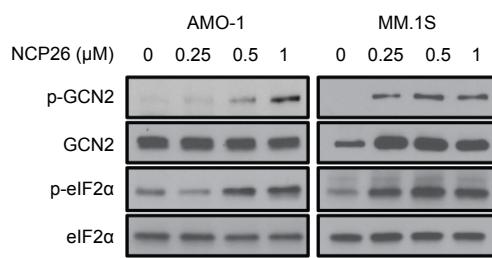

Figure A.2: Western blot demonstrating dose-dependent NCP26 canonical ISR activation with GCN2 and eIF2 α phosphorylation. AMO-1 and MM.1S myeloma cell lines used. Experiment performed by international collaborators on a multiple-lab collaborative research paper[265].

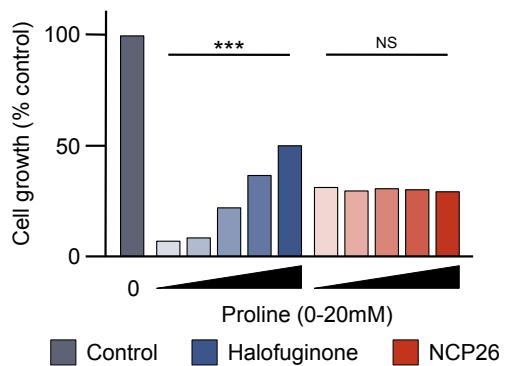

Figure A.3: ProRS inhibitors supplemented with excess proline. AMO-1 cells treated with 500nM of halofuginone or NCP26 for 48 hours in the presence of varying concentrations of proline (0, 1, 5, 10, and 20 mM). Experiment performed using triplicates. Bars represent mean cell viability. Experiment performed by international collaborators on a multiple-lab collaborative research paper[265].

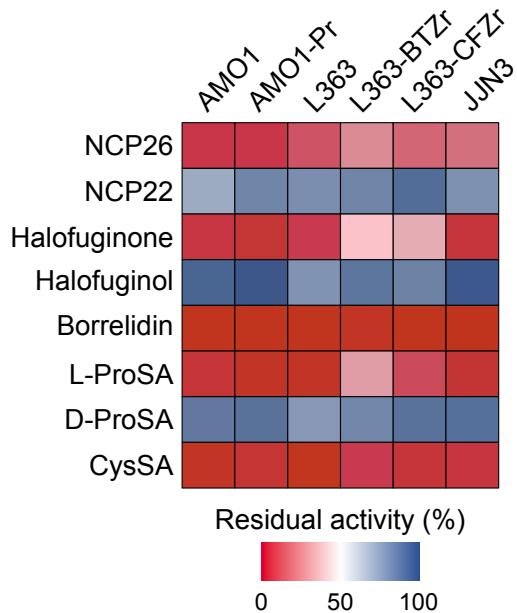

Figure A.4: Anti-proliferative activities of aaRS inhibitors in MM cell lines. Experiment performed by international collaborators on a multiple-lab collaborative research paper[265]. 1µM NCP26, NCP22, halofuginone, halofuginol (MAZ1805), borrelidin (threonyl-tRNA synthetase/ThrRS inhibitor), or 5 µM L-ProSA, D-ProSA and CysSA (aminoacyl adenylate substrate analogues). 72 hour MTT assay, n=2-5 independent experiments in triplicate technical repeats).

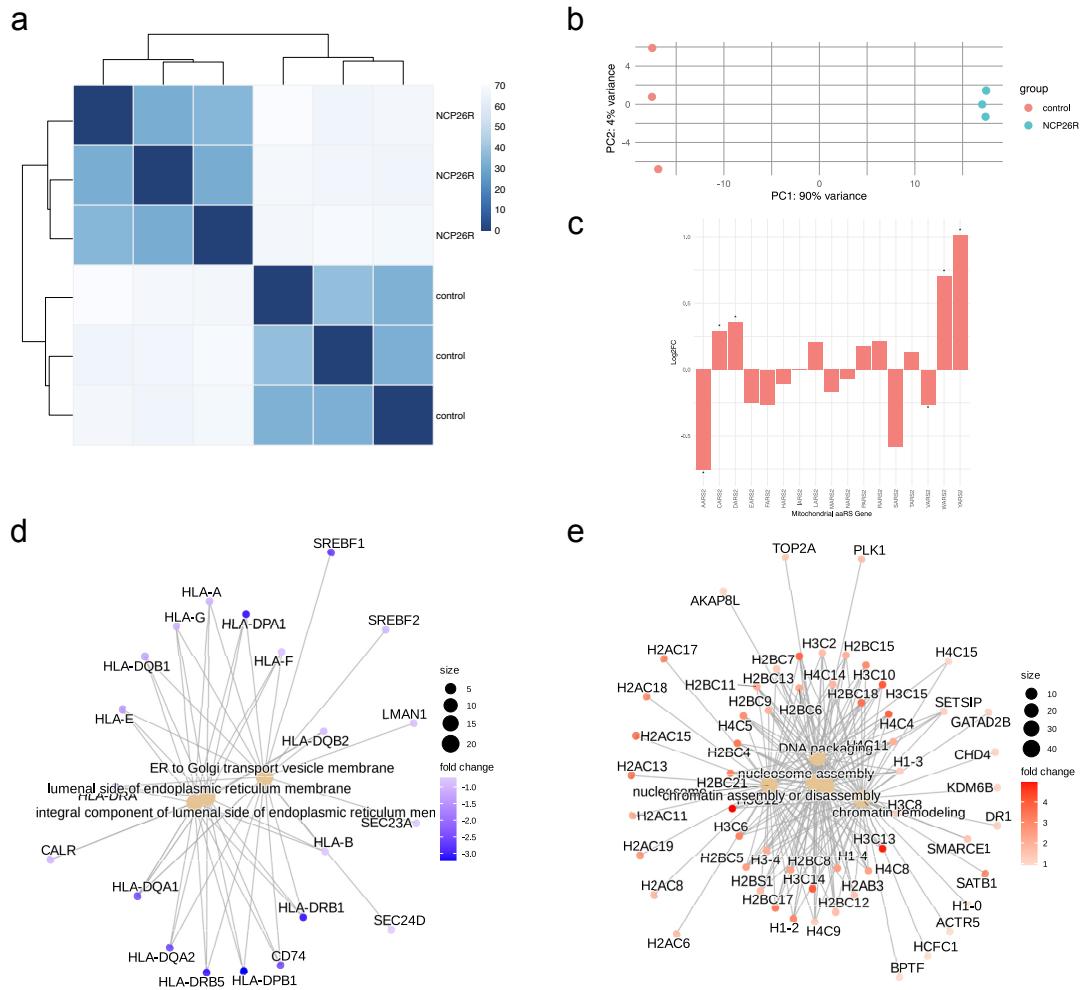

Figure A.5: NCP26R vs control L363 bulk RNA-seq. a) and b) sample clustering. a) PCA plot- separated across PC1 into two distinct groups: control L363 samples and NCP26 resistant (NCP26R) L363 samples. b) Sample-sample distance clustering. c) Mitochondrial aaRS gene Log2FC L363 controls vs NCP26R. Stars indicate differential expression at $p_{adj} < 0.05$. d) GSEA CNET plot for suppressed ER-associated pathways. e) GSEA CNET plot for top enriched pathways. Numerous activated DNA packaging pathways and many histone genes upregulated.

Cell type	Markers
Multiple myeloma cells	CD138, CD38 (lower than plasma cells), SLAMF7, BCMA, KRAS, IGKC, IGCL2. Reduced/ no CD20, CD19, CD45 expression.
Normal plasma cells	CD38, CD19, some BCMA
B cells	CD20, some CD19
T cells	TRAC, CD3D
Cytotoxic cells	GZMH, GZMB, GZMA, PRF1
CD4+ T cells	CCR7, SELL, TCF7 and T cell markers
CD8+ T cells	CD8A, cytotoxic markers and T cell markers
NK cells	KLRB1, KLRC1, KLRF1, CD16 and cytotoxic markers
Dendritic cells	CD1C, FCER1A
Monocytes	CD14/CD16, CD68

Table A.1: Manual annotation markers for cell types originating from transcriptomic profiles of bone marrow samples. SLAMF7, BCMA, KRAS, IGKC and IGCL2 are very highly expressed by MM cells, but are not exclusive to this cluster. MM patient CD45⁺ immune cells scRNA-seq marker annotation can be found [293].

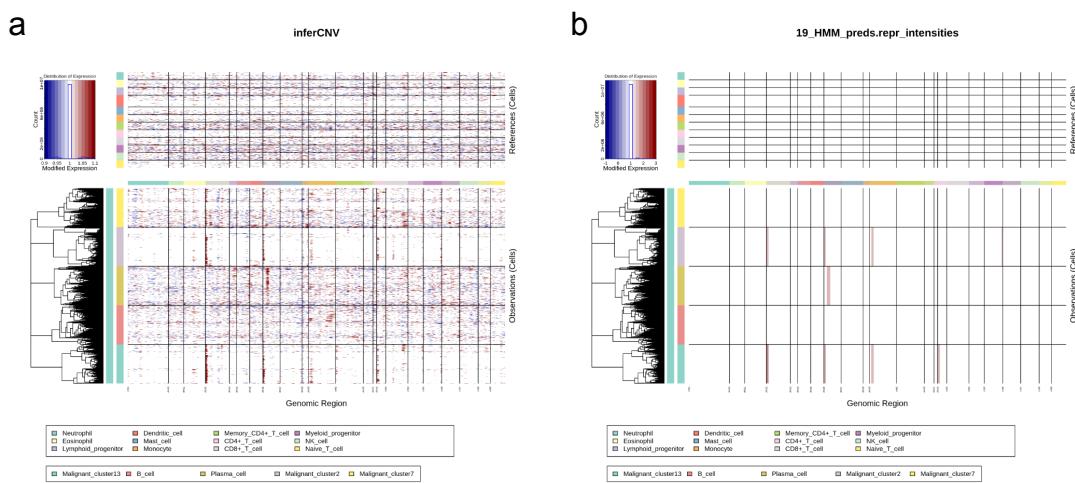

Figure A.6: InferCNV results for the newly-diagnosed MM dataset. [a and b] InferCNV heatmaps. The top panel shows expression values for the reference ‘normal’ cells. The bottom panel shows expression values for the suspected malignant cells (clusters 2, 7 and 13), and other B-cell lineages (B cells and plasma cells). Red indicates chromosomal region amplifications and blue indicates chromosomal region deletions. a) De-noised inferCNV results. b) Hidden Markov-Model (HMM) copy number variation (CNV) region predictions. Only some chromosomal region gains predicted in MM clusters 2 and 13, and the plasma cell cluster.

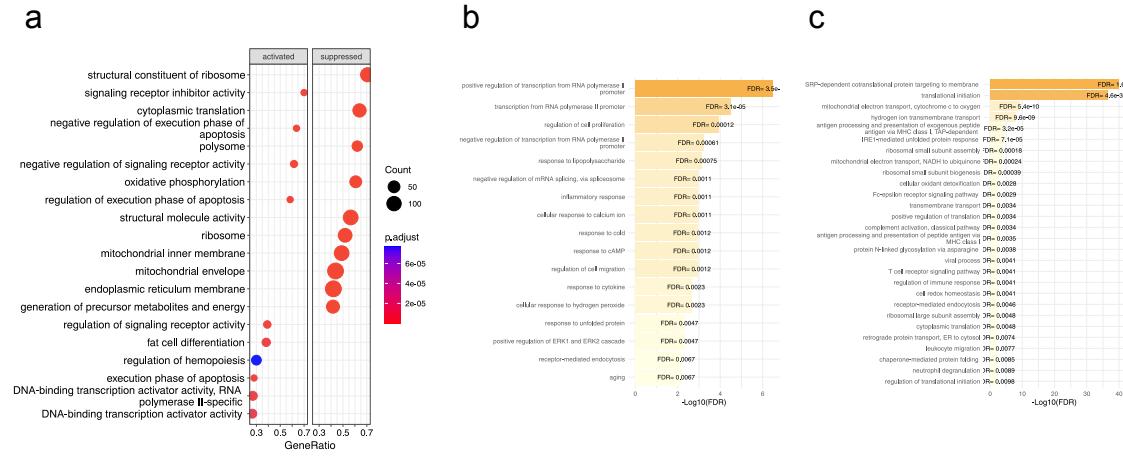

Figure A.7: scRNA-seq relapsed MM subclones (cluster 4 and 9) pathway enrichment analysis. Cluster 4 (ProRS inhibitor sensitive) vs Cluster 9 (ProRS inhibitor resistant at given experimental conditions). a) ClusterProfiler gene set enrichment analysis (GSEA) dotplot. b) XGR gene ontology biological processes (GOBP) for top upregulated genes ($\log_2 FC > 0.5$ and $p_{0.05} < 0.05$). c) XGR gene ontology biological processes (GOBP) for top downregulated genes ($\log_2 FC < -1$ and $p_{0.05} < 0.05$). Unfolded protein response is suppressed, as well as ER-associated pathways. Negative regulation of apoptosis execution is enriched.
